In the United States dermal sensitivity tests have been widely used, and brucellosis is sometimes diagnosed from a positive test found in a patient with symptoms suggestive of the disease. In deprecating this practice the committee points out that 10–25% of healthy people give positive skin tests, and that the number of positives is directly proportional to the number of infected animals in the area. Few of these people give a history of the disease, and there is not even much correlation between the severity of proved infections and the degree of sensitivity. Skin tests thus do not help the clinician in diagnosis, although they may have a place in epidemiological studies since there is little doubt that the dermal reaction is specific for brucella. In this country skin-test antigens have fortunately never been much used, although intravenous brucellin is still thought by some clinicians to be of value in treating the disease.

VENOUS VELOCITY

THE therapeutic possibilities of anticoagulants have made the study of venous blood-flow and its influence on venous thrombosis of unusual interest. Dr. Payling Wright and her colleagues have been studying the conditions under which the flow of blood in the veins may be accelerated or retarded, and they describe some of their results in an article which we publish this week. They have estimated the mean rate of venous blood-flow in the legs by injecting a minute quantity of radioactive sodium into a vein on the dorsum of the foot and then timing its arrival at the femoral triangle by means of a Geiger counter. They had previously found[1] that, compared with a standard rate of flow in the horizontal position, the linear velocity in the leg veins was reduced to half by standing and to two-thirds by sitting, but, strangely enough, it was uninfluenced by sitting with legs crossed. In this position the upper knee is higher than the groin, and this may make up for any speed lost in the dependent part of the leg below the knee. They also showed that in a sloping head-down position the rate of flow in the leg veins might be doubled, and that active movements of the foot could produce the same result.

Their latest work shows that merely putting a patient to bed does not lead to slowing of the venous blood-flow in the legs. In the paralysed legs of hemiplegics, however, venous flow is grossly retarded to about one-third the normal rate; and after surgical operations the rate of flow gradually decreases during the first two weeks in bed.[2] The reason may be that pain and discomfort cause the surgical patient to lie exceptionally still. Similarly, respiratory discomfort may make the patient with heart-disease immobilise his limbs completely. This retardation of flow must obviously favour the onset of thrombosis, but Dr. Wright and her associates have demonstrated that a little pedalling movement of the feet may make all the difference in accelerating flow through the veins.

Veins seem to have been neglected by physiologists, who perhaps regard them as passive conduits of little interest compared with the arterial system with its fascinating hæmodynamic problems. Moreover, in clinical medicine, occlusion of the arteries of the limbs is relatively easy to recognise, and its effects are readily measured or predicted. By contrast, thrombosis of veins in the legs may proceed insidiously, and its extent is almost impossible to assess; but its treacherous embolic consequences inflict appalling damage or sudden death. To minimise the risk of these disasters, the simple precaution of encouraging foot movements in bed, the value of which is underlined by these experiments, should be accepted and applied. Much suffering and disability may thereby be averted.

FINDING TUBERCLE BACILLI

IT is well to recall from time to time that the bacteriologist is not infallible, and that failure to find tubercle bacilli in the sputum may not mean that there are none to be found. The results of sputum culture depend both on the technician's skill and the methods he uses. There are, for instance, many different ways of homogenising sputum. To clarify the conflicting reports on their merits, the Public Health Laboratory Service has carried out an extensive investigation, the results of which have now been published.[1]

Four methods of homogenisation were compared by 12 laboratories, using over 3000 samples of sputum, and the thoughtfully designed and carefully executed experiment has given a clear-cut answer. The sodium hydroxide method proved a convincing winner; 28% of the microscopically negative sputa that were homogenised by this method gave positive cultures, against only 16% by trisodium phosphate, the least efficient method.

In the difficult matter of estimating progress in pulmonary tuberculosis, repeated examinations of sputum cultures, laryngeal swabs, and gastric washings give the clearest picture of the true state of the bronchial secretions. But they remain merely estimates, subject to chance errors of sampling and to inaccuracies inherent in the laboratory methods. Thus, differences between the reported rates of sputum conversion at two centres may be caused by different laboratory methods and not by variations in treatment. A patient may be classed as "non-infective" simply because trisodium phosphate was used, and not sodium hydroxide; or a "minimal lesion"—a clinical concept with no pathological basis—may seem to progress from quiescence to activity because of a change in laboratory technique, or indeed merely by chance. In clinical practice diagnosis is based on reasonable probabilities, and certainty can rarely be achieved. More efficient laboratory methods will help the physician in the difficult task of assessing these probabilities; but, on the other hand, his ideas on the management of tuberculosis may require considerable modification should the bacteriologist become able unfailingly to detect the presence of the tubercle bacillus.

OVERSEAS APPOINTMENTS

AT present hospital consultants and S.H.M.O.S who accept short-term appointments overseas must resign their posts in the National Health Service. Though their superannuation rights can be protected, they cannot claim reinstatement in their posts on their return to this country. They are away too long for their appointments to be filled by locum tenentes; nor can regional hospital boards fill these vacancies by short-term appointments, for no period of tenure can be inserted in contracts for officers of these grades. This insecurity has, not unnaturally, discouraged recruitment to overseas posts; but the Minister of Health—like the rest of us—thinks that it is in the "national interest and that of medicine generally that candidates for overseas posts should be forthcoming in this country." He has accordingly modified the present arrangements (R.H.B.[52]106) so that regional boards may grant leave of absence without pay for a period not exceeding three years to consultants or S.H.M.O.S who wish to take up posts overseas, and to fill these vacancies boards will be allowed to make appointments for a limited time.

Public Health

THE NOTIFICATION OF DISEASE

With Special Reference to Infectious Disease

E. D. IRVINE
M.D., D.P.H.
MEDICAL OFFICER OF HEALTH, EXETER

IN presenting the following survey, I hope to demonstrate the interdependence of the two great divisions of medicine, therapeutic and preventive; to show that the doctors' powers of observation and notification are vital in the campaign for public and private health; and to suggest an increased potential in the power of notifying disease, together with further collaboration between the various sections of the profession.

The Present Position

Before 1889, a few administrative authorities in this country recognised the value of the notification of certain infectious diseases, as cases occurred, to public-health departments, whence preventive measures could be instituted against the spread of disease. Notification, however, was neither compulsory nor nation-wide, and when it first became statutory in 1889 by the Infectious Disease Notification Act, it did not apply to London and was adoptive elsewhere. Ten years later, notification of the diseases listed became generally compulsory. It had been made compulsory in London in 1891. Other diseases have been added to the list mainly by regulations made by the Minister of Health under the Public Health Act, 1936, and the corresponding London Act (which repealed these earlier laws) and under preceding Acts, and by the Food and Drugs Act, 1938. Some which have been notifiable are no longer so. Apart from industrial diseases made notifiable by the Factories Acts (dating back to 1895) and by regulations made by the Minister of Labour, only infectious diseases or conditions which are believed to be frequently infectious are subject to statutory notification.

The list applicable throughout the country at present includes under the Public Health Act, 1936, smallpox, cholera, diphtheria, membranous croup, erysipelas, scarlatina or scarlet fever, typhus, typhoid, enteric or relapsing fever; under the Food and Drugs Act, 1938, food-poisoning; and under current regulations, the dates of which are included in parentheses, plague (1900), acute primary pneumonia, acute influenzal pneumonia, malaria (whether naturally acquired abroad or in this country, or if artificially induced in an institution, when the disease is likely to be a source of risk to others on discharge), dysentery (all 1927), ophthalmia neonatorum (1928), measles and whooping-cough (1940), meningococcal infection, acute poliomyelitis (paralytic and non-paralytic), acute encephalitis (infective or post-infectious) (all 1949), puerperal pyrexia (1951), leprosy (1951), and tuberculosis (1952).

Notification of some diseases may, however, be limited to persons in certain areas, or to persons of certain ages, and applied only for a defined period. Thus, although the Public Health Act, 1936, omitted puerperal fever and continued fever from the existing list of notifiable diseases, the corresponding Act for London continued the requirement to notify them. Acute rheumatism in children under 16 years of age is required to be notified in Bristol, Sheffield, Lindsey with Grimsby, and Lincoln, since 1947, and now Salford, Hull, and Cornwall; and infectious jaundice (at all ages) in East Anglia was made notifiable in 1947 for three years, but renewed. Criteria of diagnosis are applied both to rheumatism and tuberculosis: thus, tuberculosis diagnosed solely by means of a tuberculin test is not notifiable.

Local authorities, including the London County Council, but excluding other county councils, have the power with the consent of the Minister, in accordance with the provisions of the Public Health Acts, 1936, to declare infectious diseases to be permanently or temporarily notifiable in their own areas, the most usual instance being chickenpox, temporarily, during the occurrence of smallpox.

What are called the quarantinable diseases are notifiable to the Ministry by port medical officers and medical officers responsible for aerodromes; they include cholera, smallpox, louse-borne typhus and relapsing fever, yellow fever, and plague. International control of these grave infections is effected by cross-information through the World Health Organisation.

Although the duty of notification in respect of any of the infectious diseases listed in the Public Health Act falls in the first instance on the head of the family, then (in default) on the nearest relatives present or in attendance, then on persons in charge of or in attendance on the patient, and then on the occupier of the building, it is also placed concurrently on the medical practitioner in attendance or called in to visit the patient; and in fact the notification is invariably made only by the practitioner. In regard to all the other diseases the onus is placed only on the doctor. Notifications must be sent to the medical officer of health of the local sanitary authority of the area in which the case is diagnosed; but there is one exception, leprosy—which must be notified direct to the chief medical officer of the Ministry of Health.

In all cases (except food-poisoning), the notification of infectious disease is made on a prescribed form (supplied gratis by the local authorities), which in respect of a tuberculosis case must be sent in such a manner that *during its transmission its contents cannot be observed.* The fee payable by local authorities is 2s. 6d., except in relation to cases occurring in a hospital or institution or in buildings occupied for the purpose of defence services, when the fee is 1s., for which variation there seems little justification.

The doctor, in all cases except food-poisoning, must notify "as soon as he *is aware* that the patient . . . is suffering from the disease" (he must notify tuberculosis "as soon as he forms the opinion"); but he must notify food-poisoning "as soon as he becomes aware or *suspects* the patient is suffering from the disease." The difference is important.

The penalty for failure to notify is 40s.

The county district medical officer of health (in London the medical officer of health of the Common Council or of a Metropolitan borough) must send within twelve hours, if possible, and a maximum of forty-eight hours (twelve hours in London) a copy of every notification of infectious disease received by him to the corresponding county medical officer. The medical officer of health must report to the Registrar-General weekly the numbers of the different diseases notified; and the latter issues, weekly and quarterly to medical officers of health, a statement detailing this information collated for England and Wales. In some areas the medical officer of health regularly and informally tells the general practitioners about the occurrence of notifiable disease in the town or district. In regard to some of the most dangerous infectious diseases (smallpox, plague, typhus, relapsing fever, and malaria contracted in England) the medical officer of health is required to notify the Ministry at once that he has had a notification. The Ministry have in the past informally requested the immediate notification of pemphigus neonatorum and of outbreaks of gastro-enteritis in maternity homes, though these are not statutorily notifiable diseases.

STATUTORY NOTIFICATION BY OTHERS

As already indicated, others besides doctors have responsibilities clearly laid upon them in regard to notification.

Under the Public Health Acts the keeper of a common odging-house must notify to the medical officer of health the occurrence of infectious disease in an inmate.

Under the Milk and Dairies Regulations, 1949, every person having access to milk or to milk receptacles in registered dairy farms, cowsheds, milk shops, &c., as soon as he becomes aware that he or any other member of his household is suffering from any disease notifiable under the Public Health Act, or dysentery or gastroenteritis, must notify the occupier of the premises who must forthwith notify the medical officer of health. Conversely, if the information reaches the medical officer of health in any other way, he must notify the occupier.

Local Acts have given various local authorities extended powers in relation to infectious disease, including compulsory notification—e.g., by parents to the head teachers of schools and Sunday schools.

Every midwife and maternity nurse (except those in hospitals with at least 15 maternity beds, and a resident doctor) must under the Central Midwives Board's rules which are made under statutory powers, notify the local supervising authority (the county borough or county council) if she is liable to be a source of infection or if she has been exposed to any infective condition.

The master of a ship and the commander of an aircraft must report to the port or aerodrome medical officer all cases of suspected infectious disease aboard during the journey.

Veterinary surgeons attending animals suffering from anthrax or rabies or glanders or farcy must inform the medical officer of health.

Justification of Notification

Notification of disease can only be justified if it serves a demonstrably useful, and indeed necessary, purpose. Clearly, it gives information as to the incidence of disease, both in regard to the rate at which it is occurring, its age and sex distribution, the time of year in which it is prevalent, and the place in which it is found. Secondly, it is essential for the immediate local control, and also in the graver cases, national and international control, of those diseases in which control seems practicable. Thirdly, it ensures that appropriate care, including if necessary hospital care, is offered; but apart from cases of tuberculosis, this element is less significant now than it was before 1948, when the local authority itself provided treatment of these diseases; even so, the health authority has duties in relation to advice in the home, home nursing, home helps, and prevention. Finally, it may be of use as a means of providing a comprehensive list of cases which then become the basis of further study, either clinically (as in acute rheumatism) or in regard to ætiology or epidemiology, or in regard to the formulation of policies relating to their control. To be effective for control purposes, notification must be statutory: it should then be complete, but we know that in regard to some diseases it is far from comprehensive. Informal notification is almost necessarily incomplete, though in some instances in respect of what is attempted it is probably nearly complete—e.g., cancer cases treated in hospital are notified fairly comprehensively to some of the regional cancer bureaux. Who can doubt that more accurate information will be obtainable in Manchester, where german measles is notifiable, on the effect of this disease in pregnancy than will be obtained by the voluntary inquiry now being made in regard to this and other diseases by the Medical Research Council?

Notification a Prelude to Control

Infectious diseases may be made notifiable either because they are very dangerous or because, though not very dangerous, their spread can be limited, which is almost always desirable.

In many infectious diseases, knowledge is far from complete as to the way in which they are spread, and action designed for control is often taken empirically and sometimes on an insecure foundation of knowledge. It is obviously particularly difficult to control diseases which are spread by direct contact, especially in the incubation period. It is much harder to predict and to control human behaviour than to control an inanimate substance like water or food. The practice regarding contacts of disease varies greatly, but control by strict quarantine of contacts is quite impracticable even though some control of contacts in relation to occupation, school attendance, and so on, is still practised.

In regard to those diseases which are notifiable under the Public Health Act, 1936, certain legal controls apply; these deal with exposure of other persons to the disease, either by contact or through clothing, bedding, &c., not adequately disinfected; attendance at school; sending of infected articles to the laundry; carrying on trade; home work (textiles); selling rags; letting rooms; travelling by public conveyance; and the compulsory removal in certain circumstances of cases of notifiable disease to hospital and their retention in hospital and the compulsory removal in certain circumstances of tuberculous patients. Much the same apply in London. These sections of the Act do not apply to those diseases made notifiable by the Minister under regulations because he has applied to them only sections 144, 145, and 146 of the Act (the notification and not the control clauses). On the other hand, diseases made notifiable by local authorities under the Act do become subject to the same controls as the other notifiable diseases named in it. Although some of these clauses appear to be no longer necessary, it is valuable that the law does control the behaviour of persons suffering from the graver infectious disorders, and those in charge of them.

Some Suggested Variations of Notification Requirements

In considering any changes in notification the questions which should be borne in mind are:

1. Is the disease serious?
2. Is its natural history well understood?
3. Does it spread quickly?
4. Is its spread controllable?

No useful steps in regard to control are practicable in regard to acute primary pneumonia, which has now lost most of its terrors; it is time we abandoned its notification. Membranous croup is no longer diagnosed separately, and it should be left out of the list. Cholera, typhus, and true "relapsing fever" are now practically unknown in England, but as they are dangerous and subject to control they should be allowed to remain notifiable. Three others are so infectious that all the susceptible contacts are likely to get the disease—namely, measles, bacillary dysentery, and probably whooping-cough. The notification of the first case in the family in any one family outbreak would be sufficient to put the health department into touch with that family. (It must be admitted it is very difficult in epidemics to follow up adequately every family concerned.) In law, the health visitor cannot notify any subsequent case, though there may be no doubt about it; some arrangement for an acceptable record of these later cases should and could be worked out. Since, however, whooping-cough is likely to be made the subject of an immunisation campaign it may be thought necessary for assessment of the results to maintain notification of *all* cases, though it is believed that notification is even now very far from complete. A saving would be necessary in respect of dysentery—namely, that whenever the case is in a food worker or a home contact of a food worker, it should be notifiable, so that "assurance might be made doubly sure."

Scarlet fever poses particular difficulty whilst the other forms of streptococcal throat infection are not notifiable. But scarlet fever is a pretty definite clinical entity, whereas streptococcal sore throat may not be clinically distinguishable from other varieties of sore throats. The risk of spread of streptococcal infections to the community seems greatest when it occurs in milk workers, maternity-hospital workers, and institution staffs generally. Erysipelas is only a risk to the public health when it occurs in such a worker or a home contact of such a worker. Apart from these cases, which should be notifiable in every instance, it would be desirable and sufficient to notify only the first case of acute streptococcal sore throat as diagnosed clinically, or scarlet fever in a family, leaving the health department to follow up the family.

Puerperal pyrexia and ophthalmia neonatorum are conditions which may be due to infective causes, for they are incomplete diagnoses: notifications are useful if they point the way to improvements in standards of maternity care, and so affect the prospects of other mothers and infants. Many feel the present Puerperal Pyrexia Regulations are too stringent; possibly up to two-thirds of the cases notified would not have been notified under the older regulations. If the doctors would state the believed cause (and this should be required) and also if doctors would take swabs in all doubtful cases—a vaginal or eye swab can easily be taken by the midwife if so directed—preferably before or early in treatment, the accurate diagnosis, which is so important from the point of view of prophylaxis and control, would more certainly be reached; and this should be encouraged. Probably, both these conditions are substantially under-notified. Notification is said to be distasteful to general practitioners because it is followed by inquiry by the local health department; but how much would the medical officer of health be criticised, and how rightly, if notification led to no inquiry and no action; that would, indeed, be proof of its uselessness.

TUBERCULOSIS

Tuberculosis is probably better ascertained than ever before. Preliminary notification (on suspicion of the disease) has been applied in Northern Ireland to tuberculosis with, it is said, considerable success. But with increasing facilities for mass miniature radiography here, there seems little doubt that notification of tuberculosis is steadily becoming more and more complete. We must realise, as must the public, that the key to the control of tuberculosis lies not only in medical care, drugs, and surgery, but in the recognition of its infectious nature. There should be no doubt of the obligation on doctors in charge of mass miniature radiography units who should be required to notify cases suspected by them to be tuberculous. Regulations, quite reasonably, exclude from notification cases diagnosed solely on the tuberculin test. In America, a classification of cases based on the apparent activity of the lesions has been suggested, some being notifiable compulsorily, others optionally, others not at all—a method likely to lead to confusion. In England, it has been suggested that cases which are infectious or require treatment should be notifiable, but this has not been adopted legally. Simple pleural effusion of unexplained origin should be a notifiable disease in view of the frequency with which it is the primary sign of tuberculosis. The secrecy attaching to tuberculosis notifications is still preserved in the 1952 regulations though its degree is not explicitly laid down as formerly: it is wrong that a person in close and continuing contact with young children could, even though affected by open tuberculosis, continue to work amongst them; but the medical officer of health is not legally permitted to use his knowledge of the notification to intervene. This should be altered.

ACCURACY AND RISK

In regard to some of the diseases—notably malaria, acute primary pneumonia, acute influenzal pneumonia, typhus, relapsing fever, typhoid fever and dysentery in food-handlers, and notifiable disease and gastro-enteritis in milk workers—the medical officer of health is required at least to take action as prescribed in regulations, and is given certain specific powers; but generally he is left free to make such arrangements as he can for the control of the disease.

Speaking broadly, effective control depends on speedy, comprehensive, and accurate notification: reasonable accuracy and reasonable speed should not be regarded as antagonistic. Where the spread of infection is slow, notification should be based on reasonable certainty; but it is worth remembering that the patient who is mobile and infectious is a greater danger to the community than the one who is laid low by the disease.

There are two questions which any doctor seeing a case of infectious disease should ask himself, after he has made his provisional diagnosis and arranged treatment: (1) is this disease a serious risk to the community? and (2) are the circumstances here likely to make for spread? And one of the most important considerations is the occupation of the patient and his home contacts. Where the disease is a grave risk to the community, as in smallpox, poliomyelitis, typhoid, or when the circumstances are such that an explosive outbreak may occur (e.g., bacillary dysentery in a food worker or streptococcal infection in a milk worker) notification should be very prompt, and reasonable *suspicion* should be enough to justify it—certainty too often comes too late. Notification by telephone, as is increasingly practised by more progressive doctors and accepted by more progressive health departments, should be not only locally agreed, but sanctioned by the law, in regard to the cases and circumstances just referred to. Today, however, many practitioners will wait until the diagnosis is verified bacteriologically, which may take anything from one to three or four days, before they notify—a delay which makes efforts at control, or even investigations, completely ineffective.

The meaning of food-poisoning should be clarified; it is often used in reference to isolated cases of salmonella infection proved in the laboratory, but it should be reserved for illness usually intestinal or gastro-intestinal, occurring in two or more persons at or about the same time, who are known to have eaten the same foodstuff at or about the same time.

THE LABORATORY

Doctors in medical laboratories, whilst they do not make the diagnosis, do give confirmation or precision to a diagnosis, and often have information about cases of both the notifiable and the non-notifiable infectious diseases, such as glandular fever, virus diseases, leptospirosis, and possibly influenza, as well as acute streptococcal sore throat, various forms of meningitis, food-poisoning, typhoid, dysentery, meningococcal infection, and whooping-cough and tuberculosis. It would be invaluable if they were statutorily, or by direction of the Minister, required to inform the medical officer of health as soon as the bacteriological or serological or other laboratory identification is reasonably secure and points to infectious disease. This is almost self-evident in regard to the Public Health Laboratory Service, which has been set up to help to safeguard the public health, even though it is not responsible for the epidemiological control of disease; indeed, in some areas, and in part, the arrangement here suggested is already in operation. The same should be applied at least to hospital laboratories, now a part of the National Health Service, and which often have information about patients not in hospital as well as about those in hospital. These latter, if infectious, are a risk in the hospital, and possibly even to the community, and in any case should be investigated.

These proposals, if carried out, would do more than anything else to make it possible to study the natural history of all kinds of infections, where alone it can be properly studied, locally and in the home.

CARRIERS

Notification does not yet apply to persistent carriers, but only to *sufferers*. This is a serious defect in regard to salmonella and shigella carriers and should be remedied. At the present time, the regulations which govern the action of the medical officer of health and local authority in regard to enteric and dysentery are under revision, and it is probable the control of carriers will be made more effective, but not necessarily their notification. Notification is not required in regard to cases recognised long after the phase of acute illness is over, though in some instances, it should be—e.g., late recognised paralysis in poliomyelitis. It is not required of doctors who may know of the occurrence of an infectious disease but who are not in attendance or called in to visit the patient, and this is sound.

Notification is not required in regard to patients in hospitals in which persons suffering from infectious diseases are received—an exclusion which was, doubtless, due to the fact that at the time (1936) fever hospitals were owned by local authorities and administered through their medical officers of health; this is a weakness largely overcome in isolation hospitals by the close relations still existent between these hospitals and health departments, relations which may not, however, persist indefinitely. But although no-one would doubt the capacity of the staff to cope with the infections, the notification of a notifiable disease arising in an isolation hospital should now be a statutory requirement. This proposal is in line with, though it goes further than, the recent recommendation of the Central Health Services Council. Although doctors in general hospitals are not exempted from the duty of notifying, they are notoriously lax in doing so.

NON-NOTIFIABLE INFECTIONS

There are very many infectious diseases which are not statutorily notifiable, in particular, infective enteritis of infancy, gastro-enteritis of unknown origin and possibly viral, influenza, common cold, meningitis of various kinds, brucellosis, glandular fever, Bornholm disease, simple infectious jaundice, leptospiral jaundice, homologous serum jaundice, pemphigus neonatorum, and the venereal diseases. During the last war, notification of alleged causal cases of venereal disease was in certain circumstances permitted (Regulation 33B). Otherwise Parliament has always refused to require its formal notification. A certain amount of transference of information about defaulters and cases where contact tracing is important goes on between clinics and health departments which have the statutory duty of aftercare.

Influenza is a disease of which the diagnosis is by no means straightforward until an epidemic is clearly on the way, but it is at the beginning of an epidemic that it is most important to know that it is occurring. It is doubtful if the notification of clinical influenza is practicable. Occasionally, laboratories get blood samples and nasopharyngeal swabs and can make a bacteriological diagnosis. Colds are so frequent and, although serious in childhood, are generally so trivial that their notification would clearly neither be practicable nor justifiable. Presumably, the spread of the common cold can only be limited by keeping the sufferers at home.

Acute gastro-enteritis, or enteritis, may be an infectious disorder or not, but if we wait until the bacteriological diagnosis is established by laboratory investigation, we have waited too long for any hope of control. In food workers (including milk workers) this diagnosis alone should necessitate notification. Curiously, the milk worker with gastro-enteritis must notify his employer, who must notify the medical officer of health, but his doctor need not. When occurring in infants in an institution or in the staff of institutions (such as day or residential nurseries, maternity homes, or hospitals) it should also be notifiable.

Probably, glandular fever, which is said to be increasingly a serious disorder and replacing diphtheria in interest, even if, fortunately, it is rarely fatal, should be notifiable. Simple infectious jaundice, homologous serum jaundice, and leptospiral jaundice are all probably commoner than is realised, and some measure of control for them seems practicable: it would seem reasonable to make them notifiable. It is now exceedingly difficult to trace the origin of brucellosis, so control (apart from pasteurisation) is difficult.

It is impossible to make regulations covering indefinite infectious diseases and yet how valuable it would be if any explosive outbreak or clearly infectious process (even if not formally notifiable, or even not completely diagnosed) were to be reported voluntarily to the medical officer of health, a reasonable fee, say 5*s*., to be payable for informing him of the outbreak. The occurrence of family epidemics is recognised by every general practitioner and more painfully still perhaps by every doctor who has a family.

Notifiable Industrial Diseases

The notifiable industrial diseases include, by virtue of the Factories Act, 1937, poisoning by lead, phosphorus, arsenic, mercury, and anthrax; by the Lead Paint (Protection against Poisoning) Act, 1926, lead poisoning in painters of buildings; by various regulations (dates in parentheses), toxic jaundice (1915), chrome ulceration (1919), epitheliomatous ulceration due to tar, pitch or bitumen, mineral oil or paraffin (1919), carbon bisulphide, aniline, chronic benzene poisoning (all 1924), manganese poisoning (1936), compressed air illness (1938), and toxic anæmia (1942).

Any medical practitioner attending or called in to visit a patient whom he believes to be suffering from any of these diseases, contracted in any factory, must notify the Chief Inspector of Factories, London, for which he receives a fee of 2*s*. 6*d*. Failure to notify carries a penalty of 40*s*.

The occupier of a factory is required to notify the factory inspector and the appointed factory doctor of the occurrence of a notifiable industrial disease in his factory, and he can voluntarily notify industrial dermatitis.

Notification is obviously required in order to direct attention to any factory in which an industrial disease has occurred so that appropriate preventive measures can be taken. It is also important in relation to those cases that end fatally because a coroner's inquest is then desirable in regard to which the Factories Act, 1937, makes special provision. The question of compensation—there are 38 statutory compensable diseases—is not related to notification.

Since the toxic effects of poisons are usually insidious these cases do not present so dramatically as the infectious diseases; and Legge suggested that any symptoms necessitating absence from work and appeal to a doctor for treatment constitute sufficient grounds for notification. He also, however, said that in some of the diseases listed—e.g., mercury poisoning—for every declared case there may easily be twenty minor cases in the shop. Quite clearly, therefore, notification should be made on reasonable suspicion.

Other Non-infectious Disease

Notification is primarily used for control. Is it desirable to extend it to non-infectious diseases where controllable factors may be apparent, and to disease in which ætiological factors of social and environmental nature may be of real significance—for example, abortion, coronary vascular diseases, peptic ulceration, diabetes, cancer (some occupational cancer is already notifiable), and even mental illness? A great deal of mental disorder is already, in effect, notified to the medical officer of health and it would be unwise at this stage to go beyond that.

Clearly, requirements to notify must be kept within reasonable limits and morbidity returns and registration of sickness cannot be regarded properly as within the scope of a discussion on notification. Notification of non-infectious disease is a most difficult problem. My own view is that in selected areas it might be tried experimentally for a limited period in the first instance for one or more diseases—say for abortion, or diabetes—or even nationally for a single disease. Inquiry should be made along pre-selected lines and in conjunction and in collaboration with the general practitioners and hospital consultants. Abortion inquiries would have to be protected in some way from police intervention—a very difficult matter. But these disorders appear to be a real justification for such an inquiry and such notification. Unless the hospitals and the general practitioners are both concerned, any notification scheme must be incomplete.

All notifications should be made in the first place to the local medical officer of health so that there would be no gaps in his knowledge of the health of the community. The necessary transfer to the Registrar-General, to the Ministry of Health, or Factory Inspectorate, should follow in a way to be prescribed. He has, too, the best opportunities for making in the home detailed inquiries necessary in epidemiological research.

If hospital consultants and general practitioners and medical officers of health, the Medical Research Council and university departments of preventive medicine, collaborated adequately, the amount of information available would be enormous. Its reduction to statistical terms would be a considerable task; but we might reasonably hope that sooner or later, in some of the diseases, preventable factors would be shown. Without such an effort, the elusive factors will probably go on eluding us, making health the sport of fate.

Leave of Absence

On Oct. 1 Manchester City Council disapproved the decision of its establishment committee to refuse the application of two doctors in their employ for unpaid leave to attend a part-time two-year course for the diploma in public health (*Manchester Guardian*, Sept. 25 and Oct. 2). The course is the first of its kind to be held at the new department of social and preventive medicine at Manchester University. Manchester Regional Hospital Board has granted leave with full pay to the members of its staff who have enrolled for the course; Salford Corporation and Lancashire County Council have granted leave at a reduced salary.

The reversal of the committee's decision was moved by Dr. William Chadwick, chairman of the health committee, who pointed out that too few doctors had taken the D.P.H., which is an essential qualification for medical officers of health. It was to the ultimate benefit of the city and to the advantage of local government that junior medical officers should be allowed to take the course. Several councillors who agreed to the granting of leave in principle objected that 2½ days a week was too long. Alderman H. Quinney pointed out that a recent applicant for an appointment as school M.O. had been asked by the education committee to take the D.P.H. For Manchester to ask for the qualification and yet refuse facilities for obtaining it was unfair; other authorities had to allow facilities and then Manchester came along and took the finished product. He reminded the council that the doctors taking the course were sacrificing £300 a year to do so.

The growing number of calls on the time of senior officers of the council was also discussed. Alderman R. S. Harper pointed out that the M.O.H. spent an enormous amount of time [illegible] London; they had to protect him f[illegible]ms on his time. Councillor J. E. Pheasey, too, held that the absences of chief officers of the council were growing to alarming proportions; in 1950–51 one of them had been away for more than half the working days of the year. Councillor L. W. Biggs thought that, though it was to the credit of Manchester to have a chief officer whose services were in such demand, six months' absence in the year was too much.

As the *Manchester Guardian* points out editorially, an officer who is taking part in the deliberations of a public body may be serving his council in absence as well as when present, for these national bodies "are often the real policy-makers of local government."

L.C.C. Health Services

Figures given in the statistical report of the London County Council health committee for the quarter ended June 28, 1952, show that the number of home confinements in the county continues to fall. In the June quarter of 1950, 3641 London mothers were confined at home; in 1951 the total was 3381; and this year it is down to 2820. Expressed as a percentage of notified live and still births in each of the three quarters, the figures are 25·1, 22·7, and 20·0 respectively. The number of first attendances at the council's antenatal clinics during the quarter fell from 6242 in 1951 to 5306 this year. It is estimated that 38% of expectant mothers received some part of their antenatal care in the clinics, as compared with 45% in the previous quarter and 43% a year ago. First attendances at child-welfare centres were also less than in the corresponding quarter of 1951.

These figures represent a continuation of the national trends noted in the Ministry of Health's annual report, which is the subject of a special article in this issue.

Slum Clearance

In his report for 1951 Mr. F. Binns Hartley, chief sanitary inspector for Wolverhampton, says that if the present rate of allocation of new houses to families from clearance areas continues, it will take 40 years to clear the borough's 6000 substandard houses. So far only those houses which have become a positive danger to life and limb have been cleared; the best that seems possible in the near future is the demolition of the 200 worst houses, but at the present rate of clearance it will take 4 years to deal with these alone.

THE EXPANDING HEALTH SERVICE

The Ministry's Annual Report

THE report of the Ministry of Health,[1] published last week, tells of the steady expansion of the National Health Service in England and Wales—an expansion hampered by financial restrictions, but an expansion none the less. The limit of £400,000,000 set on health-service expenditure for the whole of Great Britain in 1951 meant that new developments and extensions of existing services could be achieved only by saving money elsewhere in the service; and the report describes some of the ways in which this was done.

The report covers the twenty-one months from April 1, 1950, to Dec. 31, 1951. These dates were chosen so that future reports could deal with calendar, rather than financial, years, thus bringing them into line with the reports of the Ministry's Chief Medical Officer and with most statistical records other than financial.

HOSPITAL AND SPECIALIST SERVICES

Though, as the report points out, figures for hospital waiting-lists must always be accepted with caution, the number of people waiting for admission fell by 27,000 in 1951—from 530,543 on Dec. 31, 1950, to 503,584 a year later—but the figure is still some 6000 higher than it was at the end of 1949. A more reliable sign of the improving situation is the increase in the number of available beds by nearly 14,000 in 1950 and 1951; the total rose from 448,057 in 1949 to 461,892 in 1951. The corresponding increase in the number of inpatients treated, as measured by discharges or deaths, was from 2,936,980 in 1949 to 3,259,214 in 1951; and there were about 150,000 more "new" outpatients in 1951 than in 1949. The report continues:

> "This development has to a considerable extent been achieved by better use of existing resources. . . . Former isolation beds are now used for tuberculosis, uneconomic units—those, for example, for the treatment of infectious diseases—have been aggregated so as to free staff and accommodation for the development of special departments, hospitals have been linked clinically as well as administratively, departments have been redistributed within individual hospitals and groups. Re-organisation within hospital groups leads to a better service and reduced costs—in some cases, for example, children's beds and maternity and gynæcological beds have been concentrated to good effect in single units. Other services, such as pharmacy, maintenance, supplies and laundry, have been re-organised on a more economical group basis. In general, the major feature of the period under review has been the better planning of the service so as to secure the fullest and most economical utilisation of all resources."

The consultant service has also grown: there were 1605 whole-time consultants in 1951, as against 1310 in 1949; and part-time consultants increased from 3879 to 4274 over the two years. The domiciliary consultant services, which help to reduce considerably the demand on beds, were called on more often; 129,538 patients were seen at home in 1949 and 171,193 in 1951.

The development of the hospital service was also shown by a rise of over 10,000 in the number of whole-time nursing and midwifery staff, and a steady increase in other professional staff—physiotherapists, occupational therapists, and so on.

Turning to the standard of treatment provided, the report remarks:

> "The developments in the service have been qualitative as well as quantitative—in other words, not only have more patients been enabled to receive treatment but individual patients have often been enabled to be treated better or more comfortably. The difference is perhaps most marked in the old hospitals where modern equipment has been installed, particularly the former public assistance institutions which have in the last two years become true hospitals with efficient consultant services and less forbidding appearance. Many of these hospitals were filled with bedridden people in 1949, but now many of the patients are being rehabilitated and made ambulant once more. These old institutions have changed their character and are recognised locally as real hospitals."

Voluntary Aid.—Gifts and legacies to hospitals increased from £1,700,000 in 1949–50 to about £3,000,000 in 1950–51, "and have helped materially to provide all kinds of amenities and in some cases equipment and services which could not otherwise have been provided from restricted budgets." The Hospitals Endowments Fund distributed over £600,000 to hospitals in 1950–51 and as much again in 1951–52.

Beds for the Chronic Sick.—The service is still in difficulties over providing enough room for the care and treatment of the chronic sick. Nearly 57,000 beds are now set aside for this purpose, but the waiting-list is still over 8800. The Ministry says:

> "The heavy demand for hospital beds for other classes of patients tends to limit the admission of chronic sick patients as the hospital service must have regard to the fact that the admission of one long-stay chronic sick patient will prevent the admission of a number of short-stay acute cases."

Suitable nursing staff are still lacking in some areas, and 3100 beds in chronic-sick wards are unoccupied for this reason.

Tuberculosis.—Beds for the treatment of respiratory tuberculosis are still scarce, mainly because of shortage of nursing staff, but the situation has much improved. Suitable blocks in general and isolation hospitals have been set aside for the treatment of tuberculosis, and closed beds have been brought into use again; by these means 3650 more beds became available between July, 1950, and December, 1951, bringing the total increase since the service began to over 6000. The waiting-list (which does not include those patients who are admitted within ten days of being put down for admission) fell from about 11,000 in December, 1949, to about 7000 in December, 1951; and moreover the length of time taken to find a bed for a patient on the list has on the average been much reduced.

Appliances.—In the twenty-one months, over a million new surgical and medical appliances were supplied, and over 117,000 were repaired through the Hospital Service. The output of hearing-aids was higher than ever before, but in spite of this the waiting-list fell by only 2000 (to 110,000) between November, 1950, and August, 1951; but by the end of February, 1952, it was down to 94,000.

MENTAL HEALTH SERVICES

There are still too few nurses and beds; and overcrowding, waiting-lists, and restrictions on the admission of voluntary patients persist. Nearly 5000 beds are unoccupied because of lack of staff. On the other hand, the beds that are in use are now showing a more rapid turnover than in pre-war years, and the number of admissions and discharges in 1949 was double the corresponding figure for 1939. The report gives two reasons:

> "In the first place, voluntary patients are coming forward to an ever-increasing extent, with the result that a higher proportion of cases are coming within reach of treatment in the early stages of illness when the prospects of successful treatment are, of course, better; secondly, there has been a notable increase in the development and application of curative treatments."

GENERAL MEDICAL SERVICES

The Ministry reports that a large number of visits made to general practitioners by members of the regional medical service have given "a general impression of increasing satisfaction with improvements which are taking place, despite inevitable complaints about some administrative matters." Where direct access to X-ray and pathological departments has been given to practitioners, they "have found added interest in their work and benefit both to patients and themselves." Such arrangements have not thrown any unnecessary burden on the special departments.

---

[1] Report of the Ministry of Health covering the period April 1, 1950, to Dec. 31, 1951. Part I. (1) The National Health Service. (2) Welfare, Food and Drugs, Civil Defence. Cmd. 8655. H.M. Stationery Office. Pp. 166. 5s.

Large surgeries were still the rule; many doctors have found "that the appreciable seasonal remission in attendances is much less marked than before the start of the Health Service," and the number of patients attending with trivial ailments was a cause of general complaint. Though few practitioners had difficulty in securing hospital admission for patients who were acutely ill, many still found it very hard to get beds for the chronic sick.

By the end of 1951 there were about 18,000 doctors in the service, and their lists totalled over 43,000,000, though this is a somewhat inflated figure.

GENERAL DENTAL SERVICES

After the introduction of charges for dentures on May 21, 1951, there was a substantial decline in the demand for false teeth, but the amount of conservative treatment continued to increase gradually. The average cost to public funds of a course of dental treatment dropped from its peak figure of £5 16*s.* to £2 14*s.* by the end of 1951.

The number of dentists in the service rose from 9495 at the end of 1949 to 9694 two years later; this "slow rate of recruitment," says the report, "gives rise to some disquiet, particularly when the high average age of the profession is taken into consideration."

SUPPLEMENTARY OPHTHALMIC SERVICES

The demand for spectacles fell sharply after May 21, 1951, when charges amounting to roughly half the cost were introduced. Before this date spectacles were being supplied at the rate of about 7,500,000 pairs a year; in the second half of 1951 the rate was down to about 3,300,000. Arrears were cleared off by early 1951, and spectacles are now being supplied as quickly as in pre-war days.

PHARMACEUTICAL SERVICES

The number and cost of prescriptions increased steadily. The chemists dispensed 217,144,505 N.H.S. prescriptions in 1950; and in 1951 the total rose to 228,585,022. The average cost per prescription went up from a little over 3*s.* 1*d.* at the beginning of 1950 to a provisional figure of over 3*s.* 11*d.* at the end of 1951. The report says that the introduction of chloramphenicol into general practice, more prescribing of other expensive drugs, and the rise in the prices of certain drugs and dressings contributed to the higher cost.

LOCAL HEALTH AUTHORITY SERVICES

Fewer mothers were confined at home in 1951; the *domiciliary midwifery service* dealt with 253,035 confinements last year, as against 270,752 in 1950 and 299,372 in 1949. The decrease is attributed partly to the falling birth-rate and partly to the growing demand for institutional treatment. In 1950 gas and air analgesia was provided in 58% of domiciliary cases, compared with 53% in 1950 and 43% in 1949.

Attendance at *antenatal, postnatal, and child-welfare clinics* also declined. The number of women who went to antenatal and postnatal clinics in 1951 was 15% less than in 1949; and attendances at child-welfare clinics fell by about 2½% in the same time.

On the other hand, *health visitors* and *home nurses* had more work to do; and the *ambulance service* received more calls than ever, though the average mileage per patient continued to fall steadily.

GENERAL PRACTICE IN REVIEW

THE annual meeting of the Executive Councils' Association for England and Wales, held last week, and that of the Scottish association in the previous week, brought to light some interesting views on general practice and other branches of the National Health Service.

OPINIONS FROM SCOTLAND

Mr. G. G. C. BAIN, retiring president of the Scottish association, which met in Inverness, remarked[1] that new brooms, in sweeping clean, sometimes collected useful material which was also consigned to the scrap-heap. Thus at the start of the National Health Service some regional boards had based the staffing of hospitals on an entirely wrong conception: the general practitioner had been unceremoniously swept out of the way, and the loss in many cases had been considerable. Mr. Bain called for a more general use of the family doctor in hospitals, and for a much closer link in the radiological service between consultant and general practitioner.

Dr. E. R. C. WALKER, Scottish secretary of the British Medical Association, said[2] that in the National Health Service Scotland had its own distinct statute and administration; yet he doubted whether the wisdom—or even the existence—of this arrangement was always appreciated. There was an obvious danger that for the sake of uniformity changes might be made which were not required by natural and organic evolution—or, more important, that changes necessitated by such evolution might be prevented. Dr. Walker observed in particular that "a distinctive feature of Scottish hospitals—the medical superintendent—may before long disappear, not because of any proven demerit, but for extraneous and largely irrelevant reasons."

> "Developments since 1948 make it quite clear, I think, that the purely administrative superintendent will disappear as a feature of hospital management in England. It is the declared objective of the Ministry of Health to reduce to a minimum the time to be given by medical staff to administrative duties. . . . It is difficult to see what is happening in this regard in England as anything other than a comparatively humane form of liquidation of the administrative medical superintendent."

Dr. Walker criticised the attitude to any proposed change which found expression in the response: "But that would mean an amendment of the Act." In this, as in other social services, considerable legislative changes must be expected in the future.

Like Mr. Bain, Dr. Walker was concerned with the imperfect integration between general practice and the hospital service. The Scottish Health Services Council, discussing this problem, had said: "We think it right to record our view that unless a full measure of integration is achieved through the existing machinery, serious consideration will have to be given to changes in the administrative framework." The reference to "existing machinery" related, among those things, to the liaison or coördination committees set up under the Act.

> "I find it difficult to believe that this arrangement can effectively contribute to the 'full measure of integration' which the Health Services Council rightly calls for. Even supposing that it could and did, is this not rather a clumsy and cumbersome way of achieving the end in view? Would it not really be at once simpler and better to eliminate the need for coördination by the straightforward process of making one administration responsible for all the medical services?"

Dr. Walker also referred to the legal liabilities of doctors in contract with administrative bodies in the service.

> "From earliest times the relationship between a physician and his patient has always been regarded as an essentially personal one and, as a corollary to the strict confidentiality

---

[1] *Glasgow Herald*, Sept. 26.
[2] *Scotsman*, Sept. 27.

thus involved, doctors have always accepted absolute responsibility for their actions. The Common Law provides safeguards against any dangers that may be inherent in this relationship. If this responsibility is now to be shifted to, or at least shared by, the administrative authority, does it not seem inevitable that this authority, which in effect means the State, will become a directly interested party in the doctor-patient relationship ? I feel quite sure that the vast majority of people in Scotland would not wish to see this come about. Moreover, I feel morally certain that it was not the intention either of the framers of the Act or of Parliament that it should. Yet the first steps in this direction have already been taken."

Mr. JAMES STUART, secretary of State for Scotland, said that last year the cost of the pharmaceutical service in Scotland was over £1 per head; the total of over £5 million was more than that paid to all the Scottish doctors. The immediate result of the charge on prescriptions had been a fairly substantial drop in the number of prescriptions dispensed, though this had been partly offset by the continued rise in the average cost of prescriptions. With regard to the dental services, it was still too early to say what savings could be expected from the new charges; but fully 40% of all patients now going to the dentist belonged to the priority classes—nursing and expectant mothers and young people under 21—who paid nothing for treatment. In the supplementary ophthalmic service the demand for sight tests seemed to be settling at a level where each year some 7½% of the population were having their eyes tested.

THE MEETING IN ENGLAND

At the meeting of the association for England and Wales, at Scarborough, Mr. IAIN MACLEOD, Minister of Health, suggested that the following trends should be encouraged:

1. Full coöperation between the general practitioner and the local authorities' domiciliary services, to relieve the pressure on beds by ensuring that patients did not spend time unnecessarily in hospital.

2. An increase in the number of partnerships and the development of practice by groups of doctors working together as teams.

3. A better distribution of doctors so as to avoid some having more patients than they could care for properly.

4. Closer association between family doctors and the hospitals, including contact with the doctor's own patients in hospital and direct access to X-ray and pathological departments.

5. The family doctor becoming the leader of a team comprising all the services provided by the local health authority according to the needs of the patient.

6. Closer coöperation between doctors, dentists, opticians, and chemists working under executive councils.

In Mr. Macleod's view hospitals should keep general practitioners in touch with their patients. Hospital staffs should be prepared to do what they could to let general practitioners have access to their patients in hospital, to keep them informed of progress and on discharge, and to discuss cases with them. General practitioners should have prompt notice of discharge and any necessary clinical details, which in cases requiring continuity of care should be given in advance. Hospitals could also help family doctors by inviting them to attend clinical meetings and by developing the already increasing provision for direct access to X-ray and pathological departments: "We shall not feel satisfied till all general practitioners have direct access to these departments." General practitioners in the smaller towns and in rural areas (and some others) in his opinion should be able to have charge of those of their own patients who did not need specialist care but needed admission to hospital; and selected general practitioners should hold specific part-time posts of various kinds.

Under the Danckwerts award, total remuneration would keep pace with the number of doctors. When a good distribution of practitioners had been secured, the Ministry and the profession would have to agree on the proper rate of entry into general practice, and arrangements would have to be made to link remuneration to that rate. "The Exchequer," said Mr. Macleod, "clearly cannot finance an unlimited increase in the number of doctors beyond the point at which the best practicable distribution can be secured consistent with the proportion of the national resources that can be devoted to this purpose."

Mr. H. C. BROWN, the president, pointed out [3] that no particular politicians or party could claim the National Health Service as their brain-child. "I think it is time that the scramble for credits ceased and that the politicians tacitly agreed that the health of our nation should be sacrosanct from party political jobbery."

DEFENDING DOCTOR AND DENTIST

THE two English medical defence societies have lately held their annual meetings, and have issued instructive and readable reports obtainable on application. The Medical Defence Union has its offices at Tavistock House South, Tavistock Square, London, W.C.1, and the Medical Protection Society at Victory House, Leicester Square, W.C.2.

Medical Defence Union

Presiding over the 67th annual general meeting on Sept. 16, Dr. S. COCHRANE SHANKS, the president, said that the council had taken a prominent part in professional affairs during the past year.

In collaboration with the British Dental Association, it had urged that under the new Dentists Act the proposed dental auxiliaries should not be allowed to undertake fillings or extractions of teeth. The Act, as passed, would allow auxiliaries to extract children's teeth; but, unless the new General Dental Council so decreed, there would be no dental auxiliaries.

With the British Medical Association it had been studying the procedure for investigating complaints from hospital patients. (Some proposals now being further considered are set out in the annual report.)

Ten years ago the Union had begun to press for measures which would prevent confusion of one kind of anæsthetic-gas cylinder with another, and considerable success had been attained. in conjunction with the Society of Anæsthetists and the Ministry of Health.[4]

> "We have reached full agreement with the U.S.A. and Canada about the colours of cylinders and non-interchangeable couplings, and at a conference to be held in Paris next month we hope to reach similar agreement with all European countries outside the Iron Curtain."

In warning members of the common hazards of practice, the President referred particularly to the hot-water-bottle burn, the diathermy burn, the too tight plaster-of-paris, and the injection of anæsthetics into an artery instead of a vein.

Membership of the Union stood at just over 37,000 on July 15 last, and 500 new members were elected in August. The accounts for 1951–52 showed a net surplus of £7630. Because of the very heavy litigation expenses incurred in 1948, the Union's indemnity policy with the Yorkshire Insurance Company has been revised. "In future the Union will be responsible for the first £40,000 in damages, opponents' costs, and settlements out of court. The Yorkshire has to take the next £40,000, and if that figure is exceeded we have to call on Lloyd's for £100,000. After that we would have to call on our own reserves, a contingency that is very remote."

---

[3] *Manchester Guardian*, Oct. 4.

[4] See *Lancet*, July 5, 1952, p. 36.

Dr. Cochrane Shanks, who was re-elected president, concluded by paying a special tribute to Dr. Robert Forbes and Dr. P. H. Addison (secretary and assistant secretary) and the other members of the staff.

Medical Protection Society

Sir **Ernest Rock Carling**, in his presidential address on Oct. 1, said that the professions must face the fact that the word responsibility was now being used in two senses. Every doctor and every dentist had always accepted *medical* responsibility for the care he gave to his patients. But *legal* responsibility now seemed to include responsibility for everything done by anyone who assisted him—the house-surgeon, the nurse, or anyone else. Some means must be devised by which the doctor could delegate responsibility without penal sanctions: how could he be responsible for every action of a junior officer whom he might not even have been allowed to choose? Such a state of affairs was impossible, and could even lead to breakdown of the work of a hospital. Another and yet more serious development was the situation in which the hospital, in seeking to clear itself from a charge of negligence, might cast aspersions on members of its own staff. What would be the relations between board and staff if this sort of thing happened?

"To err is human," said Sir Ernest; "but I am bound to add that there is nothing about the law in our courts which is divine or forgiving." And, by taking more thought, mistakes and difficulties could sometimes be avoided.

Some dental surgeons, he felt, had a slightly casual attitude towards the casual (and even regular) patient. There should always be records, and where there had been some mishap a note should be made that the patient had been told about it. For surgeons and physicians careful records were equally important.

Whoever was making an injection ought to verify its nature by personally reading the label on the bottle or ampoule—even when he was presented with the fluid by someone else. Care must also be taken to see that ampoules taken out but not used were not put back in the wrong box. And before giving an intravenous injection one must be quite certain that the needle is in the vein.

Anæsthetists must recognise the extreme importance of ensuring that taps and valves were in order—neither too stiff nor too easily turned on—and of preventing a harmful drag on the arm of a patient under a relaxant drug.

Certain accidents of practice, such as a slip on the floor, might come under the heading of third-party risks; but, wherever there was doubt, members of the society could be sure they would get the benefit of it. "Let there be the slightest slur on the professional reputation of a member, and we shall deem it our business to defend him."

The 60th annual report shows that, for the sixth successive year, expenditure exceeded income; and Mr. W. M. **Mollison** held that the rise in subscription last January, from £1 to £2, was fully justified. With a membership of over 27,000 last December, the expenditure per member was £1 8*s.* 3½*d.* The society's financial resources amount to about £150,000, and it is reinsured with Lloyd's for any sum exceeding about £11,600 which it might have to pay by way of costs and damages in any year.

Sir Ernest Rock Carling, Mr. Mollison, and Dr. Alistair French were re-elected president, treasurer, and secretary, receiving in each case the very warm thanks of their colleagues.

> ". . . Whatever the method of improving humanity and of raising men to a higher position than they occupy today may be, and whenever and however the millennium may be reached, it is not to be reached by declaring in favour of class consciousness and class antagonism, hatred between one class and another. The problem we have to solve is an educational and moral problem. No political constitution can enfranchise a people, no possessions can enrich them, no rank or title can ennoble them, unless they have solid, manly character and wholesome honesty, as the granite rock upon which they are built."—Sir Edward Grey, 1910; quoted by Ann Bridge.

In England Now

A Running Commentary by Peripatetic Correspondents

In New Zealand we are conscious of our insularity, and one of the manifestations of our isolation is the way in which we pounce on every incomer and question him closely about his country of origin and his journeyings. In London we find that our appearance from the other side of the world is accepted as commonplace. Such acceptance is of course refreshing, but I wonder if those who greet the travellers so casually do not miss much of interest.

Lately we took advantage of a beautiful day to go by water to Greenwich, and we thoroughly enjoyed the sight and sound of so much that was deeply familiar though never before visited by us. As we sat on Greenwich Pier, working out our return plans from a bus map, a grubby little Cockney joined us. She proved adept at maps and soon we knew just where she lived, where Mother did the shopping, and where to find various aunts and uncles. As we were now good friends I thought she might be interested to tell her school mates that she had talked with folk from the ends of the earth; so I inquired if she knew the map of the world. "Oh yes, we've done it at school." "Do you know where New Zealand is?" "Down by Australia." "We have just come from there." "Have you?" and she hastened on to leave an uninteresting subject with, "Have you any more maps of London?"

* * *

Your correspondent who was horrified by hearing his own recorded voice may be interested to hear that his dismay is often shared by professionals. Many of the actors and singers whom I have met in my laryngological practice admit surprise, pleasant or unpleasant, on hearing their own voices "played back." The reason is of course, that in real life we never hear ourselves as others hear us. But if allowance is made for microphone distortion, particularly at high pitches and great intensities, and if the singer or speaker has used his full voice—rather than murmuring into the microphone and relying on amplification to achieve volume—recording can enable us to hear ourselves for the first time. In the ordinary way we hear our own voices partly by bone conduction through our own skull and this usually increases the richness of timbre. For the same reason otosclerotics, with normal cochleæ, often speak in a quiet and gently modulated voice. The performer's voice may of course be further distorted by the acoustics of the hall or auditorium; the voice which is reflected back to him may differ in quality from the tones heard by the audience.

* * *

Many of us open-air types in the West Country are gravely concerned about the virtual disappearance of our English partridge. Where we used to get 15–20 brace on the first day out we now get only one or two. We guess at possible causes: lack of keepering, increase of vermin, the use of artificial manures, open trapping, "intensive" farming which repeatedly disturbs nesting pairs, destruction of eggs by tractors, and so forth. All these doubtless play their part and are largely inevitable. There is however another possibility about which I should like to have an authoritative opinion. Here the buzzard is a protected bird and its numbers have increased enormously. It is unusual in the course of an ordinary country round to see fewer than half a dozen of these handsome creatures either circling the sky or perched on telegraph poles. Are they perhaps wreaking havoc among the young broods? If so, is it not time that they were deprotected? Of course possibly the partridges don't mind either way.

* * *

I have been doing some research into the Smile Factor in hospital staffs. This was prompted by a remark of our maid that she liked the West African nurses at the local hospital "because they were always smiling," and was made possible by my own admission for a minor operation to one of our London teaching hospitals. During a stay of three nights, with one subsequent outpatient visit, I met 27 members of the hospital staff and noted the number who smiled at the first time of meeting (excluding 2 porters who put me on to the

the theatre trolley, as I was too sleepy to notice or record them). Of these 25, 12, or 48%, smiled the first time we met. Good, I thought; but perhaps not quite good enough? Of course a statistician would boggle—they are all born bogglers—at any comparison with other hospitals or groups; for they would claim that other factors were involved, such as whether the observer smiled first (an apprehensive and propitiatory grin seldom left my face); whether the patient was known to be a doctor—but which way would that work? —or even on the state of the weather. There is also the difficulty that a smile may *sometimes* be such a *frigid* and automatic grimace that it is less welcoming than a cheerful, friendly, but technically smile-less approach.

Breaking down the figures, I find that the percentage was higher in the older age-groups, showing perhaps that training is in the right direction. Hospital porters appear to be an exception to this, though the sample was small (3). More research is needed—haven't I heard that phrase before somewhere?—and the King Edward's Hospital Fund might offer a challenge cup.

* * *

We know what the M.R.C. investigators say about their famous experiment on the Scottish island. *They* say that the *pedigree virus* they brought from Salisbury had grown too tame to bite, and that their susceptible volunteers would have remained quite healthy and happy if they hadn't chanced to catch a wild cold from a crofter on the mainland. That's what *they* say; but that's far from being the story told by the people on the Sutherland coast. What the inhabitants say is that when this experiment began they were a peaceful and contented community, tending their sheep, and stacking peat, and maybe catching a few cuddies or a sculloch off the rocks of an evening. And then suddenly the M.R.C. let loose from Eilean nan Ròn a cold so terrible that its memory will live in the minds of their children and their children's children. That's what the crofters say; and I know it's true, because that same cold has been travelling down through Scotland and England and I caught it myself last Saturday. Whatever may be averred about harmless domesticated viruses, I for my part shall always take care to gargle after meeting any member of the M.R.C.

* * *

Even advertisements are bigger and better in the States. Last month, for instance, a well-established American medical agency advertised for a medical man, skilled in surgery, "especially in appendectomy," with a wife, also medically qualified, experienced in obstetrics and gynæcology. They are wanted by a *mysterious foreign potentate* "in a far-off sultry land" to attend the royal household, location unspecified, which comprises four wives and a harem. Both doctors must be American-born graduates of a class-A medical school, and they will receive $50,000 annually, all expenses paid, free of U.S. income-tax, and live in the palace. The only snag stated is that water is so scarce that the ladies of the harem have to bathe in perfume. The potentate is said to be "enormously wealthy, and very American-minded." He has an American chauffeur and an American business adviser, and lives on American food. Perhaps that is why he needs someone at hand who is a dab at appendectomy.

Why can't we have jobs like this advertised in the "Miscellaneous" section at the back of THE LANCET? Who wants whales when he could have camels?

* * *

"In the short time at my disposal I shall be unable to refer to the work which . . . or to those interesting . . . or even to . . ." How often have we heard a speaker waste a precious half-minute in so excusing himself for some unimportant omission. The alternative formula "the time allotted to me does not permit . . ." is usually accompanied by a hard and reproachful glance at the organising secretary. If every participant in a scientific meeting agreed to discard these almost invariably employed platitudes, there would be time on each programme for one more paper or for an additional ten minutes at that important coffee-bar where friendships are made and ideas exchanged. Speakers should follow the excellent advice of Lady Mendl: "Never complain, never explain."

Letters to the Editor

THE CRIMINAL AND THE INSANE

SIR,—It is one of the fundamentals of English law that no prisoner is tried if he cannot defend himself adequately, or at all, by virtue of mental disease or defect. Yet the same prisoner can be incarcerated as a criminal lunatic without having been convicted of any crime. There are said to be *many* inmates of Broadmoor who insist that they are innocent of any offence and who deeply resent their detention as criminal lunatics. Some of them have committed suicide, others might have preferred execution, but few would not have elected to stand their trial. What would they have had to lose?

A prisoner, without necessarily being mentally abnormal in the legal sense, often takes little or no part in his defence. The conduct of the case is left to legal experts, and legal assistance is provided for those who cannot afford it or would dispense with it. Would it not be more just, reasonable, practical, and humane therefore to allow all prisoners accused of murder to stand their trial? Their mental state and the degree of responsibility could be assessed after a verdict had been reached.

There are many lunatics who have no homicidal tendencies. Should not those who commit murder be executed? Generally speaking, crimes are not committed by lunatics but by criminals who are mad. As a psychiatrist I am naturally in favour of the treatment of lunatics, but I am not unmindful of the fact that there are good and bad lunatics. I have little sympathy for the criminal who is insane. He is a far greater menace than his mentally normal contemporary. Professionally I have encountered only two murderers who were, in my view, insane. The histories of both these men revealed criminal tendencies and behaviour long before there was any evidence of insanity. A case could certainly be made out for the execution of murderers who are mad. My professional conscience is more concerned with the prevention of further loss of innocent lives than it is with the survival of a homicidal lunatic.

Many murderers in their early twenties have been executed. Some of them had no previous criminal record, yet there was no question of attempting to convert them into useful citizens. Why then do we expend time, energy, brains, and money in efforts to cure criminal lunatics? If this was done solely in the interests of science, it would be sound and practical; but it is nothing of the kind. Murderers who are found to be insane are not executed, because we are civilised and humane—but we are not humane enough to abolish capital punishment or attempt the regeneration of mentally normal murderers.

Enemies of society should be used for the benefit of society. Endeavour to cure them by all means, or experiment on them if you like; but the execution of the normal and the reprieve of the lunatic constitutes an inconsistency which is devoid of all intelligence and humanitarianism.

London, W.1. ELLIS STUNGO.

SIR,—After over twenty years' experience in psychiatry, including six years with the Industrial Neurosis Unit at Belmont Hospital, I feel that something must be done to safeguard the community from the menace of the aggressive psychopath.

I am prompted to write this letter by the fact that during the past few months a number of aggressive psychopaths, either after discharge from hospital or while out of hospital for a few hours, have been charged with murder or attempted murder. On reading the records of the offenders, when apprehended, it is clear that many if not all of them are aggressive psychopaths.

Of the patients admitted to the Industrial Neurosis Unit at Belmont Hospital 75% are psychopaths, and many of these are of the aggressive type. Their histories for the most part show many points in common. They are often illegitimate or come from broken homes (the main factors in the production of psychopathy being, in my opinion, lack of the security and affection to which all children are entitled); they are brought up in orphanages, become delinquent in childhood (often with sadistic practices), and thereafter graduate through approved schools and Borstal to prison.

I am one of those who hold that psychopaths are made by their early environment, and I do not regard the hereditary aspect as important. I believe that if these children could be placed in reasonable foster-homes, where they could have security and affection, psychopathy could in many cases be avoided. I am also convinced that once a psychopath always a psychopath, and that when their antisocial characteristics have become ingrained only prolonged treatment may remove these deep-seated habits. They are embittered, refuse to work, and prefer to maintain themselves by criminal means, resorting to violence if necessary to achieve their ends. But as they are not psychotic, they cannot be certified; and punishment in prison or elsewhere has little or no deterrent effect on their antisocial propensities. Intellectually they show no impairment; indeed their level of intelligence may be quite high.

Dr. Maxwell Jones has been attempting in the Industrial Unit to resocialise these psychopaths by group therapy. The whole unit, consisting of 100 patients, exists as a therapeutic community, and the patients and staff live as an integral group. They share their daily activities, and work out their tensions and difficult situations; and in this way the patients may gain insight, acquire a social conscience, and realise their duty to the community. But although in some cases the results are promising, in many the outlook is hopeless. One reason for the lack of success is the fact that the patient will not remain in hospital long enough for resocialisation. Hence many aggressive psychopaths are again turned loose on society and continue their lives of crime and violence.

We know that terms of imprisonment do not help in the least: they only embitter these people further and make them if possible more antisocial in their behaviour. We have to admit, too, that as things stand, the psychiatrist can seldom help such patients. I would like, therefore, to suggest an alteration in the law relating to them.

In Holland and Denmark for some time it has been the practice to send criminal psychopaths, under a court order, to an institution where they remain for life if necessary and which they are unable to leave unless they are held to have recovered from their illness. It would surely be to the advantage of society if such a colony were set up in this country to which criminal psychopaths (after being diagnosed as such by a panel of responsible psychiatrists) could be sent and where an attempt could be made, under more hopeful circumstances, to resocialise them by group therapy and community life. I would suggest that, though the patients would be sent there on an order of the court, the institution should be run more on the lines of a hospital than on those of a prison and that the staff should consist of psychiatrists interested in social aspects of their specialty, with nurses and social workers trained in the same sphere, while ancillary workers such as psychologists, occupational therapists, and trade instructors would also be employed. Also the colony should be largely self-supporting, for many of its departments could be staffed by the patients.

So long as these psychopaths are free agents, and can leave hospital whenever they want to do so, the chances of resocialising them are small. Legislation under which they could be detained would be of benefit both to society and to the psychopaths themselves.

Belmont Hospital,
Sutton, Surrey. LOUIS MINSKI.

** Denmark's experience with a prison for criminal psychopaths has been described in these columns by Dr. Stephen Taylor (*Lancet*, 1949, i, 32).—ED. L.

REPORTS FROM CONSULTANTS

SIR,—While I agree that unnecessarily large numbers of patients are referred to hospitals, it is nevertheless disconcerting, to say the least, if patients turn up at the surgery a week or more after their discharge from hospital, and the doctor has not received a report on their condition or the result of the investigation. Moreover, some reports simply recapitulate, with certain refinements, the patient's symptoms, and then conclude by stating that a certain line of investigation has proved negative.

May I quote two letters on a patient, a young woman, who has had flatulence, frequent loose motions, and loss of weight for about a year?

(1) "I think this patient has a chronic alimentary tract infection and I will treat her in my clinic for a while and report to you again."

(2) "I saw this patient again yesterday afternoon and I think she is beginning to respond to treatment."

London, N.W.6. W. LEVY.

CURE OF TOBACCO-SMOKING

SIR,—Life is indeed simple for Dr. Lennox Johnston. Tobacco-smoking is an addiction; addictions are bad; therefore tobacco-smoking ought to be abolished. Undoubtedly it is the duty of the individual practitioner to point out the disadvantages of smoking to the individual patient when occasion demands, but before committing the medical profession to a wholesale condemnation of smoking we must attempt to answer two questions: (1) What is the cause of mass addictions? (2) What is the balance of the good and evil effects of such addictions and of tobacco-smoking in particular?

Dr. Lennox Johnston provides the clue to an answer in his observation that smoking is not enjoyable until addiction has become established. In other words a strong need is artificially created, and the means for satisfying it are kept within easy reach.

The existence of civilised society is only possible through the constant control and abnegation of individual urges, and civilised life from birth onwards is a continuous chain of sacrifice of immediate satisfactions in order to qualify for, and make possible, the enjoyment of the advantages of organised social existence. Mass drug addiction is a highly successful artifice which grants the individual the repeated feeling of immediate gratification of urgent desires without bringing him into conflict with the codes and purposes of society. Before tampering with such a tremendous safety-valve we should consider the alternative. The activities of abstemious fanatics in various periods of history do not make a very reassuring study, and it may moreover be doubted whether a policy of freedom from all addiction and its equivalents could be successfully imposed for any length of time upon the majority of a civilised community. A fiscal or medical policy designed to eradicate tobacco-smoking would have to provide an acceptable and less injurious alternative or accept the moral responsibility for the consequences. Surely the tobacco addiction of the 20th century is preferable to the alcohol addiction of the 19th as being considerably less disruptive to the physical, moral, and economic health of the community. It might be wiser to concentrate on the question of how smoking can be made even safer than to tamper with a complex mass psychological phenomenon which in this century has found a fairly acceptable outlet. Even if smoking increases the chance of a man developing cancer of the lung from 1 in 10,000 to 1 in 1000, it remains questionable whether community or individual have anything to gain from the abolition of smoking. The chances of drowning increase even more steeply with the acquisition of the ability to swim, and it may after all be better to be a smoker than a swimmer. I do not assert that this is so; but nobody, and certainly not Dr. Lennox Johnston, has tried to draw up a correct balance.

It might be argued that we should strive to remedy the imperfections of society which render mass addictions necessary; but I believe that the need for such addiction is not primarily caused by faults in the social system but is of the very essence of civilised existence with its inevitable tension between the short-term urges of the individual and the long-term objectives of society. The medical profession must act upon human nature as it is and not as it might be.

There will always be cases in which smoking has to be discouraged. But there are many non-smokers to whom the best advice that a doctor can give is that they should get a pipe and dissolve some of their soul- and body-destroying frustrations into blue smoke.

Edinburgh. ERICH GEIRINGER.

SIR,—Gluttony, one of the seven deadly sins, is now, like most of the other six, excused by psychologists and encouraged by advertisers. Dr. Lennox Johnston would have us classify smoking among the vices of addiction. But addiction to food does as much to fill the graveyards; and, although it does not dissipate scarce dollars as smoke, it preserves calories bought with hard currency as massive subcutaneous monuments to uninhibited alimentary lusts.

The surgeon who has to fight his way into the peritoneal cavity is justified in wishing that his patient had eaten less and smoked more. Would Dr. Johnston now use his considerable talent for polemic in the cure of addiction to eating?

Chelsea. AUBREY LEACOCK.

SIR,—There is no great difficulty in stopping smoking provided one applies ordinary common sense.

(1) The patient must have a real desire to stop smoking.

(2) This is often effective after an illness.

(3) Having decided to stop, fix a date five days hence—four days is not long enough, six days is too long. Make the patient realise that on the fixed date all forms of smoking must cease. In the meantime get him to carry out the following breathing exercises: inhale slowly and fully, pause for five seconds, then exhale forcibly; repeat six times. The pause will ensure that CO_2 will produce the same effect as smoking—increased CO_2 tension in the alveolar air. This exercise can be repeated as often as desired. Breathing should be entirely nasal, unless there is some obstruction. At the same time concentrate on the date fixed. This treatment should suffice for patients of ordinary intelligence.

But most cases one has to treat individually, and either direct or indirect methods must be applied. For example, a direct method would be used when a patient comes in with a glossitis or leucoplakia. "This condition is not serious in itself, but in a smoker it may lead to something serious." If necessary, produce some literature from a reliable source: quote Fourier of Paris and Kelly of Baltimore as arriving at the same conclusion that the condition was not of any great importance unless there was a collaborator—and that collaborator was tobacco.

The indirect method can be tried on a patient interested in sport or in his personal appearance. A golfer can be told that his putting has deteriorated because of smoking: quote Bishop Harman, and, if necessary, show him the book about the deterioration of vision and irregular formation of writing produced by smoking. "Stop the puffs and slot the putts."

Again, women patients may like to smoke and also remain attractive. Well, they just cannot have both. Advise them to visit a few women's bridge clubs, where they will always see one or two excellent examples of nicotinism. Tense expressions, faces the colour of a spade guinea, trying desperately to augment their incomes, or at any rate trying to avoid losing.

I am an ex-chain-smoker who used to average 40 cigarettes a day. Seventeen years ago I stopped as the result of a challenge by a drug addict. I stopped smoking at once and have never smoked since. I am glad to say that I am still friendly with many hundreds of ex-smokers whom I helped to give up the habit. I have lost a number of patients through refusing any treatment unless they stopped smoking. "Do you think my catarrh has anything to do with smoking, doctor?" "Yes." "Can't you give me something to stop this cough unless I give up smoking?" "No." But I must avoid getting too involved in the subject, for I know well that any attack on the tobacco-smoking habit is always followed by a counter-attack with a definite purpose.

PRACTITIONER.

OCCUPATIONAL ADAPTATION OF MENTAL DEFECTIVES

SIR,—The research on this subject was both interesting and useful, and the report by Dr. Tizard and Dr. O'Connor (Sept. 27) should be studied by all concerned with mental deficiency. It is, therefore, a pity that they allow themselves conclusions on more general matters. Mental-deficiency hospitals are not maintained for the sole purpose of occupational training, but for the whole care of whole individuals of many types and with many needs. Thus, the authors' dislike of large hospitals, which is not necessarily justified even from the point of view of training the feeble-minded, takes no account of the whole problem, the small supply of trained staff, and the cost to the community, already in financial difficulties. It is unfortunate, also, that they should publish such sweeping criticisms without stating their evidence; and that they do not distinguish between the faults (or virtues) they see in policy and design, and those things which are due to the conditions of the time.

It is true that many more hostels are needed for the finishing stage of high-grade patients who are nearly ready for licence, and that such hostels can be run very cheaply. But this is offset to some extent by the increased cost of the parent institution which is left with a greater number of non-productive patients. After years of education by those in the service the authorities have begun to accept the principle of hostels, but most hostels have still to be found. New houses cannot be built, old ones do not always stand where they are wanted, and, as usual, there is no money. Again, the small number of social workers is not due to any failure of method or principle but to the inadequate birth-rate in the 1930s which provided too few girls for the increasing number of jobs which now need them. Commendation is given to the great increase in daily licence at Darenth, and it is mentioned that this is part of a general movement, which is true. But it is only in part due to a general improvement and liberalisation of policy within the hospitals: it is also due to the fact that it has now become easy to place patients in outside jobs which they could not have got before the war.

The statement "The *widely recognised shortcomings* of the mental-deficiency service formed the starting-point of the research" creates a moment of anxiety as to the absence of bias with which scientific research should be conducted. The anxiety is revived when one finds the questionable statement "*with very few exceptions* institutional *policy* has not been to return defectives to the community but to segregate them." The italics are mine. This is known to have been true of some places in the old days and it is believed to be still true of a few hospitals which have not moved with the times. It is certainly not true of some, and I should need facts before accepting the criticism with respect to others of which I know something.

I remember Douglas Turner, some 25 years ago, insisting that the patients in an institution were not to be likened to a stagnant pool but to a flowing stream. The flow is inevitably slow but, as Galileo said, "Eppur se muove." It is a pity to have spoiled a piece of good work by straying too far.

St. Albans. NOEL H. M. BURKE.

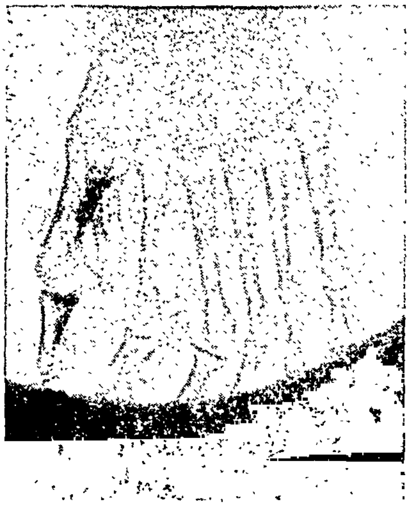
HÆMOPHILIA

SIR,—We are being asked by many doctors to collect in one centre all the relevant information on hæmophilia and allied subjects. We shall be very grateful, therefore, if authors would put the International Hæmophilia Society, 94, Southwark Bridge Road, London, S.E.1, on their mailing-list for reprints.

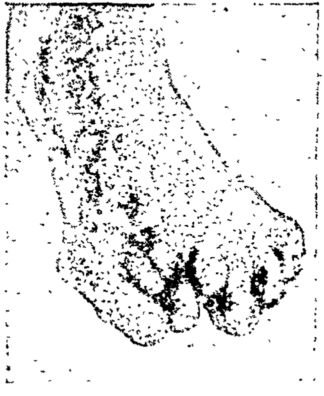
FRANK A. SMITH
President, International Hæmophilia Society.

CONGENITAL ABNORMALITY OF THE FOOT

SIR,—In a village in Gambia, British West Africa, a man aged about 25 years was examined whose left foot had nine formed toes and a small appendage on the dorsum, which had been present from birth.



His gait was normal and he stated that he was not inconvenienced in any way by the deformity. The posterior part of the foot appeared normal, but the anterior part was very broad and had a marked hallux valgus. The lateral part of the foot with the lateral four toes, and the great toe, were normal; but between the two were four extra toes (see figure).



Radiologically, the lateral four toes and metatarsals appeared normal as did the great toe and the first metatarsal. One of the abnormal toes had three tarsal bones and a normal metatarsal bone. Two of the other abnormal toes also had three tarsal bones, but had very short metatarsals. The fourth abnormal toe had only two tarsal bones, and associated with it there was a head of a metatarsal which tapered abruptly to a point posteriorly. The dorsal appendage had no osseous structure. The medial cuneiform was either greatly enlarged or there was a closely associated accessory bone lying between it and the intermediate cuneiform.

The right foot and both hands were normal clinically and radiologically.

A CHEAP SURGEONS' CAP

SIR,—To have recourse to Authority, even to one as eminent as Sir Holburt Waring, in branding a new idea as bad never was a very convincing argument; and I feel that on this score the outright condemnation by Mr. Whittingdale last week of Mr. Howkins's fisherman's jersey bonnet (Sept. 27) must be viewed with suspicion.

On the other side must stand the host of surgeons whose eyebrows have stood exposed despite possible falls of dandruff, and without septic consequences. Drops of sweat indeed are usually a much more frequent dropping than flakes of dandruff, and in the solving of this problem Mr. Howkins's cap seems a reasonable suggestion.

In any case, is there any reason why Mr. Whittingdale should not introduce his own modification of the Howkins cap by pulling it over his eyebrows?

Ballochmyle Hospital,
Mauchline. IAN A. MCGREGOR.

MEGALOBLASTIC ANÆMIA

SIR,—Dr. Foy and his colleagues[1] have discussed the response to oral penicillin in four cases of megaloblastic anæmia. *Cases 1 and 2 were treated with 100,000–200,000* units per day, while cases 3 and 4 received 800,000 units daily. The first two cases had certain features which appear significant to me.

These are the visible icterus, the high blood-bilirubin level, the subnormal mean corpuscular hæmoglobin, and the reticulocyte-counts of 1 and 1·5%. In
are distinct enough to point to a
active megaloblastic hyperplasia wc
These may be described as case
hæmolytic anæmia," where the marrow is hyperplastic and the cells are of the normoblast or macroblast type; and, "even when deeply basophilic, primitive forms are found, they do not show the peculiar scroll-work type of nuclear chromatin which is characteristic of many of the nucleated red cells in the marrow of pernicious anæmia and related forms of macrocytic anæmias."[2] Therapeutically classified, they *belong to the group of anæmias which are amenable to* treatment with sulphonamides, antibiotics, or surgery.[3]

In the first two cases penicillin has halted the excessive peripheral blood destruction, with consequent remission in the anæmia as shown by the return of the findings to normal. It is likely that, in these two cases, the marrow contained cells which have been variously named "macroblasts," "macronormoblasts," "transitional megaloblasts," and "unfinished" or "precoctic" cells. Despite these varied names, I think they all describe the same cell. I consider that their presence in the marrow indicates a sustained and profound stress resulting in what may be called intermediate erythropoiesis, the significant cell being neither a megaloblast nor a normoblast in structure. In such cases the emphasis in treatment is on intercurrent pathology rather than on anti-anæmic measures. Sometimes anti-anæmic measures are not *necessary.*

The sole finding in case 3 indicative of a megaloblastic anæmia is the active megaloblastic marrow; for the peripheral blood is of the normocytic, normochromic type. I find this disparity difficult to explain.

Case 4 appears to be a true megaloblastic anæmia of the dyshæmopoietic type in the early stages of a *relapse.* Since the mean corpuscular hæmoglobin is on the increase, the visible icterus and the high bilirubin content of the blood should not be taken to indicate hæmolysis; these findings are made often enough in pernicious anæmia, so that it was once thought that pernicious anæmia had a hæmolytic origin.

It would be interesting to speculate on the response of cases 1 and 2 to the larger doses, and of cases 3 and 4 to the smaller ones. I feel the result would have been the same, and submit that Dr. Foy and his colleagues lost a very good opportunity of proving their point. They might have treated cases 3 and 4 on the small-dose scheme when the larger one proved futile.

2. Wintrobe, M. M. Clinical Hematology. London, 1951.
3. Sturgis, C. C. *J. Amer. med. Ass.* 1949, 141, 969.

Penicillin given by mouth is absorbed mostly from the duodenum, while in the lower reaches of the intestinal tract more is destroyed than is absorbed. The concentration of the antibiotic in the colon is negligible, while in the ileum the concentration may be a little higher. Can the drug, in such poor concentration, effect any far-reaching changes in the flora, either for good or ill ? It has been proved that antibiotics of wider spectra have a tendency, with long-continued administration, to produce symptoms attributable to intestinal sterilisation and vitamin deficiency. Can the same be said about penicillin, whether given by mouth or by the intramuscular route ?[4] In conditions like lung abscess and empyema, requiring prolonged administration of penicillin in large doses, these complications have not been evident, even when no vitamins were given.

On the question of a high-carbohydrate low-protein diet being responsible for the production of inimical microflora, I wish to observe that the Brahmins of South India commonly eat this type of diet; and I have come across only a very few cases of megaloblastic dyshæmopoietic anæmia in this community. The majority of them are strict vegetarians.

Trichinopoly, South India. M. S. NARAYANAN.

SALT-WATER BOILS

SIR,—Deep-sea fishermen suffer from a septic condition of the wrists and forearms known as " salt-water boils." It is due to friction of oilskin sleeves on forearms sodden with salt water. An additional abrasive element, especially in the case of bosuns, is sludge brought up with the catch from the sea bed. I am collecting information in order to obtain :

(a) Official recognition as an occupational disease in the schedule.

(b) Uniform medical certification in the interests of sufferers.

(c) Adequate treatment at sea in accordance with the Ministry of Transport's *Ship Captain's Medical Guide 1946*, amendment no. 4.

I shall be grateful if any doctors handling these cases would write to me.

4, Hamilton Terrace,
Milford Haven, Pembs. W. BURNETT EVANS.

CHROMATOPHOROTROPIC HORMONE

SIR,—Dr. Sulman [5] has lately given his opinion on the identity of the chromatophorotropic hormone. He assumes that A.C.T.H. contains several factors, one of them being chromatophorotropic.

The mechanism of the so-called Konsuloff reaction was discussed in a recent article.[6] In 1934 Konsuloff [7] suggested that the melanophore hormone in the urine could serve as a reliable pregnancy test; and this test, based on the colour change of the hypophysectomised frog (*Rana esculenta*) after injection of urine, has been widely adopted in the Netherlands. What is the substance in the urine of pregnant women that causes the frog's melanophores to expand ? Which organ, during pregnancy, produces this substance in excess—the hypophysis or the placenta ? Is the long-known hypophyseal chromatophorotropic hormone (C.H.) identical with the hormone in pregnancy urine ? Is the latter substance identical with choriongonadotrophin ?

The identity of C.H. from pregnancy urine with choriongonadotrophin (Ch) (which, in view of the close parallelism in excretion of C.H. and Ch had suggested itself very forcibly) was rejected in 1949, among other reasons because impure 'Pregnyl' (Organon), a Ch-containing preparation, had a lower minimal effective dose for C.H. activity than very pure pregnyl. Contamination of pregnyl by a substance with C.H. activity might explain this discrepancy. When at the beginning of 1951 a small quantity of A.C.T.H. ('Cortrophin,' Organon) was placed at our disposal, it became clear to us that with this preparation (which is not free of other hypophyseal factors) expansion of the frog's melanophores could be brought about. The contaminant of pregnyl might, then, be A.C.T.H. As we did not have at our disposal " crystalline " hypophyseal hormones we tried to determine the minimal effective dose of several hypophyseal gonadotropic preparations and that of A.C.T.H.[8]

For reasons that we are explaining elsewhere, the identity of C.H. with luteotrophin (Squibb) (prolactin) or luteinising hormone (L.H.) did not seem improbable. Therefore we determined the minimal effective dose of luteotrophin, cortrophin, and pregnyl (a very pure Ch put at our disposal by Messrs. Organon Ltd.). The results were as follows:

Preparation	*Strength*	*Minimal effective dose (µg.)*
Cortrophin	.. 50 I.U. (16 mg.)	0·2
Luteotrophin ..	.. 1000 I.U. (54 mg.)	5·4
Pregnyl	.. 20,000 I.U. (43 mg.)	4·0

This shows that the C.H. activity of the preparation containing prolactin (luteotrophin) might be due to contamination by 5–10% A.C.T.H. That the pregnyl used contained this amount of A.C.T.H., is disclaimed by the manufacturers, who say that at the most traces might be found.

Even more important was the observation, which had hitherto escaped our notice, that the type of colour change was different, according to whether A.C.T.H. or pregnyl was injected. After injection of A.C.T.H. the *whole* body of the frog becomes dark. After injection of pregnyl (Ch) the hind legs of the frogs become dark, in contrast with the upper part of the body, which remains bright. This colour pattern cannot be brought about by giving cortrophin. The same colour change is also obtained with urine and blood-serum of pregnant women, 'Gestyl' (Organon) (pregnant mare's serum), and a watery extract from the frog's hypophysis. 'Ambinon' (Organon) (thyrotrophic-gonadotrophic hormone), gonadotrophin (Squibb), and luteotrophin gave the colour change of the type given by A.C.T.H. That we were indeed dealing with two substances with C.H. activity in the two groups was furthermore proved by our finding that the C.H. activity of our substances giving a colour change of the pregnyl type disappeared after half an hour's boiling at pH7, whereas the C.H. activity of the group which gave the colour change of the A.C.T.H. type appeared to be proof against this treatment.

Konsuloff's pregnancy reaction, then, in our opinion, is based on the presence of choriongonadotrophin in pregnancy urine. The chromatophorotropic activity of the hypophysis may be caused by A.C.T.H. on the one hand, or on the other hand by a substance which we think must be identical with prolactin and/or luteinising hormone. Experiments in which hypophyseal preparations are stripped of C.H. activity of the A.C.T.H. type, while the C.H. activity of pregnyl (choriongonadotrophin) type is preserved have confirmed the existence of two substances with C.H. activity. Injections of deoxycortone acetate 1 mg. and of cortisone ('Cortone,' Merck) 0·25 and 1 mg. did not give any colour change. Deoxycortone *made the frogs ill.* In our opinion the physiological significance of the C.H. activity of A.C.T.H. is not yet fully understood.

Treatment of prolactin with alkali [9] destroys the A.C.T.H. We injected prolactin treated in this way in frogs, and we found a positive Konsuloff reaction and a negative Galli Mainini spermiation test. In our opinion this suggests that prolactin possesses chromatophorotropic activity.

Notes and News

DANISH HOSPITALITY

On Oct. 2 members of the National Association for the Prevention of Tuberculosis and of the Anglo-Danish Society met to hear a report on the first year's working of the scheme, made possible by the generosity of the society, whereby British children with tuberculosis are sent to Denmark to receive free treatment at Vordingborg Sanatorium. The children are selected by the medical committee of the N.A.P.T., and Dr. Harley Williams, the secretary-general, explained that the first 25 children who went to Denmark in March were drawn mostly from London, but another 25 who had just left for Denmark came from Cornwall, the Midlands, Wales, Scotland, and East Anglia. Of the first party 14 had now returned to their homes greatly restored in health. All the arrangements had worked smoothly and the parents were satisfied and enthusiastic about the scheme. Sir Michael Kroyer-Kielberg, chairman of the Anglo-Danish Society Fund, said that it was the intention of the fund to send an increasing number of children to Denmark in the next few years. Dr. Niels Sjorslev, medical director of the Danish National Association for the Fight against Tuberculosis, described Denmark's successful fight against tuberculosis from the opening in 1875 of a sanatorium for scrofulous children to present-day methods of control which include a country-wide network of chest clinics backed by B.C.G. vaccination. In proposing a vote of thanks to him Sir John Charles happily contrasted the war-like invasion of England by the Danes so many centuries ago with the smaller return invasion this year when British children were overwhelmed with kindness and hospitality by the warm-hearted Danes.

SPASTICS NEEDING HELP

In the last ten years children with cerebral palsy have been receiving some public attention; and not before it was time. The numbers of spastics (so called) in Great Britain have been variously estimated at 20,000 and 30,000, and some 10,000 of these are children; but there may well be more, *since, of course, the condition is not easy to diagnose in infancy.* Most children with cerebral palsy are normal mentally, and all of them can benefit from training, beginning in childhood (the earlier the better), in the use of their muscles; but so far the provision made for such training is very scanty.

In a film, *The Chance of Their Lives*, the National Spastics Society have tried to show how great the need is; and they have had the good luck to get Wilfred Pickles to tell the story. The film shows how badly these children are handicapped when among normal children; and how greatly they benefit from training in special schools such as St. Margaret's School at Croydon. There are, however, only six such schools in the country at the moment, and only one spastic child in ten can hope to get a place. To illustrate the usual fate of the untreated case the film shows a young man with a severe degree of cerebral palsy applying hopelessly for one job after another, and being turned down on his appearance alone. Spastic children outnumber blind and deaf children by about 2 to 1; yet almost all blind and deaf children are taught in special schools.

The film is intended for general showing, and all will wish it well. It reveals sympathetically and pleasantly what children born with cerebral palsy have to face, as well as what friendly and likeable children they generally are.

University of London

Dr. Arthur W. Proetz, professor of clinical otolaryngology in Washington University and president of the American Board of Otolaryngology, will deliver the Semon lecture at 5 P.M., on Thursday, Nov. 6, at 1, Wimpole Street, W.1. He will speak on Clinical Aspects of Respiratory Air Currents.

Whitley Councils

The following have been nominated as members of the staff side of Committee C of the Medical Whitley Council for the session *1952–53*:

W. G. Clark, J. Cottrell, H. K. Cowan, Doris A. Craigmile, J. M. Gibson, C. E. E. Herington, E. Catherine Morris Jones, A. Macrae, B. R. Nisbet, J. Riddell, J. A. Stirling, J. A. Struthers, J. B. Tilley.

The following deputy members have also been nominated:

H. D. Chalke, H. M. Cohen, I. G. Davies, G. Matthew Fyfe, J. Kelman, J. Sharpe, Gladys Stableforth, H. C. Maurice Williams, R. C. Wofinden.

Royal College of Physicians of London

On Nov. 6, Dr. R. R. Bomford will deliver the Bradshaw lecture at the college, Pall Mall East, S.W.1. He will speak on Changing Concepts of Health and Disease, with Particular Reference to "Psychosomatic Medicine." Prof. A. A. Moncrieff will deliver the Charles West lecture on Tuesday, Nov. 11, on Infection in the Newborn Baby. Both lectures are at 5 P.M.

Royal College of Surgeons of England

Faculty of Dental Surgery.—Sir William Kelsey Fry has been re-elected dean.

British Postgraduate Travelling Fellowships

The British Postgraduate Medical Federation invites applications from doctors and dentists for these fellowships, which have been set up to enable graduates who are in the course of training as specialists in one of the preclinical or clinical branches of medicine, surgery, or dentistry, to obtain experience of the methods of practice, education, and research at universities or other centres in the United Kingdom and abroad. Further particulars will be found in our advertisement columns.

Society of Apothecaries of London

A course of postgraduate lectures on Modern Methods in Treatment is to be held in the hall of the society, Black Friars Lane, Queen Victoria Street, E.C.4, at 3.30 and 5 P.M., from Nov. 3 to 6. The speakers will be: Mr. T. Holmes Sellors, Sir Geoffrey Todd, Sir William Gilliatt, Dr. Kenneth Harris, Sir Horace Evans, Mr. A. Dickson Wright, Dr. Robert Forbes, and Dr. R. Hale-White. Admission is free, without ticket.

Heberden Society

On Saturday, Oct. 25, at 10 A.M., at B.M.A. House, Tavistock Square, London, W.C.1, Lord Horder, the president-elect of the society, will deliver the Heberden oration for 1952. He is to speak on Rheumatism—a National Problem.

University College, London

Sir Geoffrey Jefferson, F.R.S., will deliver the Rickman Godlee lecture at the college, Gower Street, W.C.1, on Oct. 23, at 5.30 P.M. He is to speak on the Prodromes to Cortical Localisation.

London's New Health Centre

On Tuesday, Oct. 14, at 3 P.M., Mr. Somerville Hastings is to open London County Council's first comprehensive health centre at Woodberry Hall, 218, Green Lanes, N.4.

Manchester Royal Infirmary Old Residents

More than three hundred members attended a dinner of the M.R.I. Old Residents Club held on Oct. 4 at Manchester under the presidency of Prof. John Morley. Prof. L. J. Witts, in proposing the toast of The Hospital and its Historian, Dr. William Brockbank, claimed for himself the distinction of having been described as "the finest student that Manchester ever turned out." Dr. Brockbank replied with a whirlwind of facts and figures about the infirmary and old residents. Dr. E. J. Foulds proposed the health of The President, and Professor Morley replied. The meeting had been moved forward a year so that it could coincide with the hospital's bicentenary year, and during the evening comparisons were inevitable but not odious. Today, for instance, there are so many resident posts that there is a net increase of about 15 a year in the membership of the club. Both of the country's surgical peers are members, and 2% of the members hold professorial chairs.

Association of Clinical Pathologists

At the annual general meeting held at Westminster Medical School on Oct. 2 Prof. R. J. V. Pulvertaft was elected president, Prof. Dorothy Russell vice-president, and Dr. Cuthbert Dukes chairman of the council. The annual dinner held next day commemorated the founding of the association 25 years ago, and eight founder members were present—A. Renshaw, E. N. Davey, S. C. Dyke, G. Hadfield, S. G. Platts, A. G. Shera, A. F. S. Sladden, and C. J. Young. The toast to The Founder Members was proposed by Dr. Dukes, and Dr. S. C. Dyke replied. Dr. W. H. McMenemey proposed the health of The Guests and Mr. Iain Macleod, Minister of Health responded. On Oct. 1 at the Constitutional Club, members of the council had given a dinner and a memento to Dr. Dyke at the conclusion of his ten years' tenure of office as chairman. Dr. McMenemey presided.

ety of Chemical Industry

a meeting of the fine chemicals group to be held at the on School of Hygiene, Keppel Street, W.C.1, on Monday, 13, at 7 P.M., Prof. F. E. King, D.SC., will deliver a lecture ie Synthesis of Simple Peptides.

criptions in August

ie Ministry of Health reports that in England and Wales ıg the month of August the declared number of National th Service prescriptions submitted was 14,075,256 :ease of 6·64% on August, 1951). The declared number of s submitted was 8,224,987 (decrease of 13·5% on August,). The ratio of prescriptions to forms was 1·71 (1·59 in ıst, 1951).

istry of Health Films

ıe Ministry has revised its list of sound films which may be hired from the Central Film Library. The films on th may be shown to lay audiences, those on medicine and ery only to medical and other professional audiences. :her particulars may be had from the library, Government ding, Bromyard Avenue, London, W.3.

idlesex Hospital Dinner

residing over the annual dinner of the Middlesex Hospital ical School on Oct. 3, Mr. David Patey said that the dlesex owed its special privileged position to being a hing hospital with university connections, responsible for graduate work. It was recognised that teaching neces- :es research, and in the present evolution of the health ice "we are splendidly poised for making advances in icine." With its established scientific institutes and its ɔwment fund (whose preservation and increase should a major concern) the hospital had a special duty and ortunity. From the standpoint of the patient, a teaching pital had its inconveniences, but the public should be ıght to understand that the special advantages they ive from being at a teaching hospital stem directly from fact that it *is* a teaching hospital. At the same time rything possible should be done to preserve the dignity the patient as an individual, by privacy or otherwise: Patey welcomed particularly the establishment of the hard Davis waiting-room for the relatives of patients who dangerously ill, and he would like to see further develop- nts in the architecture of the wards. Looking at the :ld more broadly, "all that has been regarded as civilisa- ı, from Marathon and Bethlehem, is in danger," he said, f being submerged in a new wave of barbarism; and we ı profession have a part to play in the intellectual refutation this barbarism as a necessary prelude to its physical ıtation." Sir Harold Boldero, the dean, spoke of the xiety many students had felt about the new Medical Act ıuiring them to hold 2 six-month house-appointments :ore registration. Long before the Act, however, the :rage number of house-appointments held by Middlesex n was $1^1/_2$; and there should be no hardship except :haps for men with families, whose case is now being ısidered. The hospital was proud to know that two dis- guished men were coming to continue their researches :re: Mr. V. E. Negus was to work in the Ferens Institute d Prof. S. P. Bedson, F.R.S., had been invited to the Bland- tton Institute. Perhaps the most important of all the velopments of the past 10–15 years, in Sir Harold's view, ıs the Institute of Clinical Research, which would be pported substantially from the endowment fund; and ıen the new extensions were opened, members of the staff ɔuld have modern facilities for pursuing ideas arising out their clinical work. Dr. P. A. J. Ball, senior Broderip holar, said that two students had represented the school well as Britain in the Olympic Games, and had all but ɔn a gold medal. For the first time, the majority of house- en were now married; and most of the others were engaged. ıis he regarded as a natural effect of the insecurity following e war; but older people seemed inclined to put it down a natural lack of forethought in the young and too much curity in the N.H.S.! The dean was reported to have said at it would of course mean the end of all social life. Mr. ichard Handley, proposing The Chairman, described r. Patey as the most honest man in London, and spoke his inquiring mind, his courage, his kindness, and his ımour. His recent nautical experiments, Mr. Handley id, had been particularly striking—perhaps the most ıportant being his demonstration (unfortunately uncon- olled) that steam does not always give way to sail.

Casualties in Korea

A recent casualty-list includes the name of Captain T. S. Hart, R.A.M.C., who has been wounded in action in Korea.

New York Academy of Medicine

Dr. Harry D. Kruse has been appointed secretary to the committee on public health relations of the academy in succession to Dr. E. H. L. Corwin, who has retired.

Lasker Awards

Among six recipients of Lasker awards from the American Public Health Association are Sir Macfarlane Burnet, F.R.S., director of the Walter and Eliza Hall Institute, Melbourne, and Dr. Brock Chisholm, director-general of the World Health Organisation.

Conference on Medical Photography

The medical group of the Institute of British Photographers is holding its third annual conference at the Royal Hotel, Woburn Place, London, W.C.1, from Oct. 10 to 12. Further particulars may be had from the secretary of the group, I.B.P. 49, Gordon Square, W.C.1.

Medical Congress at Evian

The second International Congress of Hippocratic Medicine will be held at Evian from Sept. 3 to 6 next year under the presidency of Professor Laignel-Lavastine. Prof. P. Delore, who is the secretary-general of the congress, may be addressed at 13 rue Jarente, Lyons, France.

British Standard for Cot Mattresses

A new British standard (B.S. 1819, part 2) has been issued for spring-interior cot mattresses (hospital type) to fit the standard hospital-type children's cots, as specified in B.S. 1694. Copies (price 2*s.* 6*d.*) may be obtained from the British Standards Institution, Sales Branch, 24, Victoria Street, London, S.W.1.

Union of St. Luke for Medical Practitioners of the Church of England

A service of commemoration of St. Luke's day will be held on Saturday, Oct. 18, at St. Stephen's Church, Rochester Row, London, S.W.1, at 3.15 P.M. After the service, at 4.15 P.M., there will be a meeting at the National Society, Great Peter Street, S.W.1, when Dr. P. C. Gibson will be in the chair and the Rev. F. S. Sinker, M.B., will speak on Coöperation Between Doctors and Clergy.

Dr. L. Guttmann, director of the Ministry of Pensions' Spinal Injuries Centre, Stoke Mandeville Hospital, and consultant to the Oxford Regional Hospital Board, is to deliver the first Fred H. Albee lecture at a conference on rehabilitation in paraplegia, to be held at the Kessler Institute for Rehabilitation, West Orange, New Jersey, on Oct. 10.

Births, Marriages, and Deaths

BIRTHS

FAWKNER-CORBETT.—On Oct. 1, at Lawn Edge, Meadowlands, Havant, Hants, to Phyllis (née Brumfit), wife of Dr. P. J. Fawkner-Corbett—a son.

HARRIS.—On Sept. 28, at Edgware General Hospital, to Sonia (née Bilmes), wife of Dr. Wallace C. Harris—a son.

HOGARTH.—On Oct. 2, at The Clinic, London, to Harriette Ruth (née Lewis), wife of Dr. J. C. Hogarth—a son.

LUNT.—On Sept. 29, to Penelope, wife of Mr. Randle Lunt, M.CH. ORTH.—a daughter.

PARKINSON.—On Sept. 29, at King's College Hospital, to Helen (née Overton), wife of Dr. Charles F. C. Parkinson—a daughter.

MARRIAGES

BOWSHER—REID.—On Sept. 27, at Liverpool, David Richard Bowsher, M.B., to Anna Meryl Reid.

PADDON—FORTESCUE.—On Sept. 20, at North West River, Labrador, William Anthony Paddon, M.D., to Sheila Mary Fortescue.

ROCKLEY—MATTOCKS.—On Sept. 20, Gerald Joseph Rockley, M.B., to Elisabeth Mary Mattocks.

RUGG-GUNN—COWAN.—On Oct. 1, at Salcombe Regis, Devon, Mark Andrew Rugg-Gunn, M.D., surgeon commander R.N., to Patricia Mary Elizabeth Cowan.

DEATHS

AITKEN.—On Oct. 2, at 'Clodiagh,' Stanmore, James Aitken, M.A., M.B. Edin.

HENDERSON.—On Sept. 29, at Ridgeway, Orchard Hill, Bideford, Devon, George Pouncey Henderson, M.D. Edin., aged 78.

LINDSAY.—On Oct. 3, at Shortfurrows, 65, Whyteleafe Road, Caterham, Surrey, Thomas Lindsay, M.D., F.R.C.S.E.

MATTHEWS.—On Oct. 3, Edgar William Matthews, M.B. Lond., D.P.H., of Oakingham, Bramber Road, Seaford, Sussex, aged 72.

SHAW.—On Sept. 29, William Samuel Jagoe Shaw, M.D. Belf., lieut.-colonel, I.M.S., retd., of Calcote House, Sandecotes Road, Parkstone, Dorset, aged 81.

Diary of the Week

OCT. 12 TO 18

Monday, 13th

Royal College of Surgeons, Lincoln's Inn Fields, W.C.2
5.15 P.M. Mr. E. G. Tuckwell: *Surgery of the Sympathetic Nervous System.*
6.30 P.M. Mr. O. J. Vaughan-Jackson: Fracture of Neck of Femur in Aged.
University College, Gower Street, W.C.1
4.45 P.M. Prof. Adrien Albert, D.SC. (Australian National University): Ionisation and Biological Activity. (First of three lectures.)
University of London
5.30 P.M. (King's College, Strand, W.C.2.) Prof. E. M. Landis (Harvard): Movement of Fluid and Dissolved Substances through the Capillary Wall. (First of three lectures.)
Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Dr. W. C. Osman Hill: Links Between Comparative Pathology and Pædiatrics.
Institute of Psychiatry, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel: Psychiatry [illegible]
Medical Society of London, 11, Chand[illegible]
8.45 P.M. Dr. Cuthbert Dukes: Your Ge[illegible] address.)
University of Edinburgh
5 P.M. (University New Buildings.) Prof. E. I. Evans (Virginia): Physiologic Disturbances Accompanying Severe Thermal Injury in Man. (First of three Macarthur lectures.)

Tuesday, 14th

Royal College of Surgeons
5.15 P.M. Sir Arthur Porritt: Surgery of Peptic Ulceration.
6.30 P.M. Mr. B. N. Brooke: Development of Surgery for Ulcerative Colitis.
British Postgraduate Medical Federation
5.30 P.M. (London School of Hygiene.) Dr. W. S. Feldberg, F.R.S.: *Physiology of the Autonomic Nervous System.*
Royal Society of Medicine, 1, Wimpole Street, W.1
8 P.M. *Section of Psychiatry.* Dr. W. S. Maclay: Deaths Due to *Treatment. (Presidential address.)*
Institute of Dermatology, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Prof. C. A. Keele: *Sweat.*
Chelsea Clinical Society
8.30 P.M. (South Kensington Hotel, 41, Queen's Gate Terrace, S.W.7.) Sir David Kelly: Russia.
Manchester Medical Society
5 P.M. (University of Manchester.) *Section of Surgery.* Mr. R. L. Newell: *Progress in Surgery. (Presidential address.)*

Wednesday, 15th

Royal College of Surgeons
5.15 P.M. Mr. Brian McN. Truscott: Alimentary Diverticulæ.
University of London
5.30 P.M. Professor Landis: Movement of Fluid and Dissolved Substances through the Capillary Wall. (Second of three lectures.)
Royal Eye Hospital, St. George's Circus, Southwark, S.E.1
5.30 P.M. Mr. J. F. P. Deller: Some Optical Aberrations of the Eye.
Royal Society of Medicine
5 P.M. *Section of Comparative Medicine.* Dr. C. L. Oakley: Sites of Production of Antibodies. (Presidential address.)
8.15 P.M. *Section of General Practice.* Dr. J. D. Simpson: Diagnosis in General Practice. (Valedictory address.)
Royal Institute of Public Health and Hygiene, 28, Portland Place, W.1
4.30 P.M. Dr. W. D. M. Paton: Uses of the Methonium Compounds. (Bengué lecture.)
Institute of Dermatology
5.30 P.M. Dr. J. O. Oliver: Bacteriology of Skin Diseases.
University of Edinburgh
5 P.M. Professor Evans: Clinical Management of Burn Shock. (Second of three Macarthur lectures.)
University of Glasgow
8 P.M. (Department of Ophthalmology.) Embryology of the Eye. (Instructional talking film.)

Thursday, 16th

Royal College of Surgeons
5.15 P.M. Mr. Geoffrey Keynes: Thymus.
6.30 P.M. Mr. J. C. Ainsworth-Davis: Surgery of the Prostate.
British Postgraduate Medical Federation
5.30 P.M. Dr. Paton: Principles of Ganglionic Block.
Royal Army Medical College, Millbank, S.W.1
5 P.M. Captain M. P. Ward: Mount Everest Reconnaissance.
St. George's Hospital Medical School, Hyde Park Corner, S.W.1
5 P.M. Dr. Desmond Curran: Psychiatry lecture-demonstration.
Royal Eye Hospital
5.30 P.M. Miss J. M. Dollar: Iridocyclitis and Choroiditis and its Differential Diagnosis.
British Institute of Radiology, 32, Welbeck Street, W.1
8 P.M. Dr. J. W. McLaren: Soft Tissue Radiography. (Presidential address.)
Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1
7.30 P.M. Prof. A. [illegible] Gastro-intestinal Function and [illegible] Sprue, Cœliac Disease, and [illegible]
University of St. Andrews
5 P.M. (Medical School, Small's Wynd, Dundee.) Dr. Leonard Colebrook, F.R.S.: Burns and Scalds.
University of Birmingham
4 P.M. (Medical School.) Sir James Spence: Poliomyelitis. (First of two Ingleby lectures.)

Friday, 17th

Royal College of Physicians, Pall Mall East, S.W.1
3 P.M. *Lord Moran: Into the Past.* (Harveian Oration.)
University of London
5.30 P.M. Professor Landis: Movement of Fluid and Dissolved Substances through the Capillary Wall. (Last of three lectures.)
Royal Socie[illegible]
4.30 P.M. [illegible] *Preventive Medicine* [illegible] Prof [illegible] Illsley: Environment and [illegible] of Social Medicine [illegible] Research in Obstetrics.
8.15 P.M. *Section of Radiology.* Dr. E. R. Cullinan, Dr. R. Kemp Harper: Scleroderma.
Institute of Dermatology
5.30 P.M. Dr. M. S. Thomson: Lichen Planus.
Faculty of Radiologists
2.15 P.M. (Royal College of Surgeons.) Mr. C. E. Drew: Intrathoracic Fibroma. Dr. G. Simon: Tuberculous Bronchitis and Bronchiectasis. Dr. Neville Oswald: X-ray Appearances of Honeycomb Lung.
University of Edinburgh
5 P.M. Professor Evans: Clinical Management of the Burn Wound. (Last of three Macarthur lectures.)
University of Birmingham
4 P.M. Sir James Spence: Poliomyelitis. (Second of two Ingleby lectures.)

Appointments

Ballantyne, J. L., M.R.C.S.: appointed factory doctor, Coventry West, Warwickshire.
Ferguson, J. H. L., M.B.E., M.A., M.B. Camb., F.R.C.S.: asst. general [illegible] [illegible]ital, London.
Mac[illegible] [illegible]B. Edin.: appointed factory doctor.
Milne, D. G., M.B. Aberd., D.P.H.: asst. county M.O., Hertfordshire.
Temple, J. Ll., M.B. Lond., F.R.C.S.: consultant surgeon, Bristol clinical area, Weston-super-Mare.

Birmingham Regional Hospital Board:

Browne, R. A., M.B. Belf., D.P.M.: consultant psychiatrist and deputy medical superintendent, Coleshill Hall Hospital.
Lane, O. G., M.D. Lond.: part-time consultant pathologist, Dudley and Stourbridge group of hospitals.
Merry, Edith, M.B. Lond., D.A.: part-time consultant anæsthetist, Coventry group of hospitals.
Stephenson, S. F., M.B. Lond., F.R.C.S.: consultant thoracic surgeon, Birmingham and Mid-Worcestershire groups of hospitals.

Leeds Regional Hospital Board:

Allison, Rhoda, M.B. Leeds: *asst. pathologist* (S.H.M.O.), Huddersfield [illegible]
[illegible] [illegible]., M.R.C.P.E., D.P.H.: consultant in chest [illegible] and Dewsbury area.
Wilson, J. E., M.D., F.R.C.S.: consultant in thoracic surgery, Castle Hill Hospital, Cottingham.

Newcastle Regional Hospital Board:

Bell, R. C., M.B. Lond., F.R.C.S.: consultant plastic surgeon (asst.), Newcastle H.M.C. group and N.W. Durham H.M.C. group.
Browarski, W. J., M.B. Polish School of Medicine, Edin., D.P.M.: resident asst. psychiatrist (S.H.M.O.), St. Luke's Hospital, Middlesbrough.
Duggan-Keen, G. E., M.R.C.S., D.P.M.: deputy superintendent, Winterton Hospital, Sedgefield.
Edmunds, A. W. B., M.B. Edin., M.R.C.P.: consultant physician (asst.), Northallerton and Darlington H.M.C. group.
Gillis, Aaron, M.B., B.SC. Durh., M.R.C.P.E., D.P.M.: consultant psychiatrist, Cherry Knowle Hospital, Ryhope, near [illegible]
[illegible] Durh., F.R.C.S.: consultant plastic surgeon [illegible] H.M.C. group and the N.W. Durham H.M.C. group.
Inglis, Alexander, M.B. St. And.: consultant pathologist, hospitals in *Cumberland and N.* Westmorland.
Noble, T. C., M.D. Edin., M.R.C.P.E.: consultant pædiatrician (asst.), Sunderland H.M.C. group.
Potter, John, M.B. *Durh.*, F.R.C.S.E.: *consultant plastic surgeon,* Teesdale and Northallerton H.M.C. groups.
Potts, R. E., M.B. Glasg.: consultant pathologist (asst.), Teesside H.M.C. group.
Prinsley, D. M., M.D. Durh.: asst. chest physician (S.H.M.O.), Gateshead H.M.C. group.
Salfield, [illegible] consultant psychiatrist, Wintert[illegible]
Strang, Chr[illegible] consultant physician (asst.), [illegible] and Berwick groups of hospitals.
Szutowicz, Stanislaw, M.B. Polish School of Medicine, Edin.: *asst. pathologist,* hospitals in Cumberland and N. Westmorland.

SPECIALISATION, STRATIFICATION, AND RESEARCH*

Sir HAROLD HIMSWORTH
K.C.B., M.D. Lond., F.R.C.P.
SECRETARY OF THE MEDICAL RESEARCH COUNCIL

It is commonly said that, because of the breadth and complexity of modern knowledge, specialisation has now become a necessity; and it is customary to continue by expressing regret that such is the case. Quite apart from the fact that no man—not even a specialist—cares to be regarded as a regrettable necessity, there are other grounds for objecting to this statement. It is undoubtedly true that the limitations of human capacity render inevitable some degree of specialisation among members of highly developed professions like medicine. But implicit in the statement are two assumptions which, if allowed to pass unquestioned, can have far-reaching consequences. The first is that specialisation arises as a reluctant, conscious response to a recognised, practical necessity; the second, that the specialisations which have now achieved sanctification as Special Subjects represent an inevitable and permanent differentiation of function within the body of medical knowledge. If these two assumptions are correct, then there is nothing to be done about the present situation but to accept it. But a consideration of the evolution of medical specialisation suggests that they may not be; and, in that case, it should be permissible to modify the boundaries and organisation of specialties as need arises.

EVOLUTION OF A SPECIALTY

Generally speaking, we can distinguish two influences tending to specialisation—research and technique. To a greater or less extent both participate in the evolution of every medical specialty, but the part played by each varies from subject to subject. Let us first consider the evolution of a clinical specialty whose characteristic is a body of specialised knowledge rather than a specialised technique.

The founders of such a specialty were general clinicians with a special interest in a system and its diseases. The incentive for them to develop this interest—to do research—was curiosity, not a reluctant realisation of their intellectual limitations; and they remained well-founded in medicine and could draw fruitfully on their general experience. In the course of time the pioneers were succeeded by another generation, but such were the opportunities in the particular field that it continued to yield a rich harvest from within its original boundaries. With each succeeding generation, however, specialisation became more intense and the links with the general body of medicine more tenuous, while, at the same time, the virgin soil, susceptible to the now traditional approach shrank.

It is not difficult to foresee the outcome of this process. As Roger Bacon said, seven hundred years ago:

> "All sciences are connected; they lend each other material aid as parts of one great whole. . . . As an eye torn out or a foot cut off, so it is with the different departments of knowledge; none can attain its proper result separately, since all are part of one and the same complete wisdom."

To counteract the inherent, and potentially fatal, tendency of specialisation to isolation is no easy task; and it is particularly difficult in regard to the clinical specialties. With the passage of time there arises, not only a body of specialised knowledge, but a system of specialised practice. What began as a convenience becomes an established institution. As such it acquires an organisation which, however favourable to its perpetuation in the original form, may not necessarily be conducive to its further development.

This consideration applies with particular force to those specialties which are bound up with a particular technique. Consider the evolution of your own specialty, ophthalmology. Serious intellectual curiosity manifesting itself as systematic scientific research hardly existed until the time of Thomas Young and did not gather impetus until the work of Helmholz. But from time immemorial empirical techniques had been practised, both by itinerant oculists and by more regular members of the medical profession. In the 19th century the intellectual and technical streams came together, but at a time when, fortuitously, circumstances favoured developments on the technical side. Anæsthesia and antisepsis were discovered and provided the opportunity for technical development. The next fifty years were, understandably, preoccupied with a search for means to exploit the opportunity thus provided. Such success attended these efforts that ophthalmology emerged at the end of this time with an exacting technical discipline which exerted, and still exerts, a determining influence upon the form of your specialty.

But what has this led to; what is the position today? Should I be far wrong if I had said the ophthalmologists now recognise that not all conditions in their specialty are likely to yield to the surgical approach; that it is the others which now constitute the major challenge to research in their field; and that they are giving anxious thought on how to deal with this situation? For dealt with it must be if ophthalmology is not to degenerate into a mere technology.

I realise that in detailing the dangers of specialisation to you I have largely been preaching to the converted; for what is the Institute of Ophthalmology but an attempt to deal with these dangers? Here you have gathered together clinicians, pathologists, physiologists, biochemists, and physicists to work in association together. This is a major step in the right direction. But I am venturing to suggest to you that such an association alone is not enough. There is, in my opinion, still an important step to be taken. We have so far been considering the dangers inherent in specialisation but I think there is another development which carries at least equal dangers. I refer to the tendency, so marked in British medicine today, which one may call stratification.

STRATIFICATION

By *stratification* I mean the confining of interests within one of the major divisions of medicine to the exclusion of appreciation of relevant happenings in others. Despite repeated criticism of the medical curriculum as artificial, it does appear that medical knowledge tends to accumulate in layers roughly corresponding to the order in which the subjects succeed each other in the medical course. Along each traditional layer communications are relatively free, and important accessions to knowledge are unlikely to remain unknown. But between those in the different layers communications leave much to be desired. Thus, although a biochemist is usually soon aware of advances in chemistry relevant to his particular interest, he often does not know of equally relevant advances in histology, in pathology, or in the clinical field. Similarly much highly relevant knowledge in pathology and clinical research remains unknown to the physiologist. Despite the importance of bacteriology, immunology, and biochemistry to pædiatrics, few pædiatricians are competent to be their own bacteriologist, immunologist, or biochemist. And how many ophthalmologists have the necessary knowledge of functional pathology and applied physiology to undertake themselves comprehensive research into those conditions of the eye associated with general rather than local changes ?

---

* An opening address delivered at the Institute of Ophthalmology on Sept. 30, 1952.

A NEW TYPE OF SPECIALIST ?

It may seem that I am denying that necessity for specialisation which I had already conceded inevitable. On the contrary I am pleading for the recognition of a further, and new, type of specialist—a specialist whose function is, not segregation, but integration. Let these men contract their interests within the particular stratum of medicine in which they find themselves—biochemistry, physiology, pathology, clinical medicine, or even a large specialty such as ophthalmology—in order to penetrate deeply into the strata on either side. Let us have, for example, clinicians who by contracting their clinical interests have liberated themselves to be competent biochemists, or pathologists, or physiologists. Such men can never supplant the clinicians, pathologists, physiologists, biochemists, and physicists proper. But that is not their rôle. They are to be complementary to these and their object is to nail together the different strata of medicine.

Let us apply these considerations specifically to ophthalmology. As a first step I suggest that two or three clinical research posts for ophthalmic physicians should be created. Many of the unsolved problems of ophthalmology are such that a man with the training, background, and outlook of a research physician would be attuned to them. Such men would in no way replace the general physicians now on the staffs of ophthalmic hospitals. Their interests would be much narrower to the end that they would be free to penetrate deeper into relevant studies in applied physiology, functional pathology, and clinical chemistry. The types of subject that I see them attacking are, for example, the degenerations of the eye (often with a hereditary basis) which develop during life, the mechanism of the retinopathies associated with metabolic disorders, and the functional changes in the eye following disorders in other systems. And quite apart from these direct contributions to ophthalmological research they would constitute a most valuable link in the chain of research-workers which stretches from the ophthalmologist proper to the basic sciences.

But do not underrate the difficulty of what I am suggesting. I am proposing, not simply that such ophthalmic research physicians be given all necessary facilities for laboratory work, both investigational and experimental, but also that they be given full staff status as clinicians with charge of research beds and responsibility for the patients under their care. Clinical research cannot be done by permission on other people's cases; nor can a practising clinician properly take responsibility for research work carried out by others on his patients.

CONTINUOUS ADAPTATION

I have chosen to take my example of the new type of specialist from the clinical field because the creation of such raises the greatest practical difficulties. But I could equally well have taken the example from the preclinical field. Both the strata and specialties of medical science are constantly tending to solidify from the crystallisation of career structures. The difficulty, and the necessity, is to keep the situation fluid so that it may be kept adapted to the opportunities of the present rather than to those of the past.

The essential thesis that I have been trying to defend is that specialisation, although a necessity in principle, is essentially an expedient in detail; that its boundaries at any particular period of time are a matter of temporary convenience; and that the condition of its healthy development is to prevent those boundaries becoming fixed and exclusive. To observe these requirements when a specialty has become embodied in a particular organisation is no light matter. But the difficulties, at least in the clinical field, are probably less now than they may be in the near future. In the precisely prescribed requirements which are now being proposed, with the best of intentions, for the training of consultants and specialists we see embodied those very dangers against which medicine, if it is to develop, must ever be on its guard; for the progress, and ultimate health, of any branch of knowledge depends upon the success with which, by preserving the elasticity of its organisation and adapting itself to new needs as they arise, it succeeds in counteracting its inherent and inevitable tendency to isolation.

INFLAMMATION AND ITS CONTROL*

A BIOCHEMICAL APPROACH

GEORGES UNGAR
M.D., D.Sc. Paris

RESEARCH ASSOCIATE, RHEUMATIC-FEVER RESEARCH INSTITUTE, NORTH-WESTERN UNIVERSITY MEDICAL SCHOOL, CHICAGO, ILLINOIS

INFLAMMATION, the commonest local reaction of animal tissues to environmental change, has been one of the basic concepts of pathology since the beginnings of medicine. However, because of its very traditional nature, the concept of inflammation remains vague and poorly understood. Morphological study of inflamed tissues, intensively pursued by generations of pathologists and histologists, has only filled in the details of the first description given by Celsus nearly two thousand years ago. During the last few decades the inflammatory reaction became an object of study for the physiologist and biochemist, and it now appears possible to formulate a working hypothesis of the mechanism by which the reaction is brought about. I present here such a hypothesis and the evidence on which it is based.

BASIC PATTERN OF INFLAMMATION

When an environmental change, whether physical (mechanical trauma, temperature, radiations, &c.), chemical ("irritant" substances), or biological (bacterial infection, toxin, venom, antigen-antibody reaction), stimulates or injures a tissue, the following reaction will develop: dilatation of the blood-vessels, increase in the permeability of the capillary walls, and migration of leucocytes toward the site of the stimulation. The result will be an initial increase in blood-flow throughout the area, followed by a gradual slowing down of the circulation at its centre, associated with the clumping of blood-cells and the formation of microthrombi. At the height of inflammation increased arterial flow and capillary stasis will coexist in what Ricker (1924) called "peristatic hyperæmia." The passage of fluid and cells across the capillary wall causes swelling of the tissue and pain, both constant manifestations of acute inflammation. The vascular reaction induces changes in other structures, particularly the connective tissue. There seems, however, to be little doubt that the blood-vessels are the site of the primary disturbance.

It is essential to distinguish the inflammatory reaction from the direct physical or chemical effects of the stimulation on the tissue. When, for example, extreme heat is applied to a tissue, several direct effects will result: loss of water, coagulation of proteins, inactivation of enzymes, loss of structure, &c. Inflammation, however, is not the sum of these changes; it is the response of the tissue to the stimulus and to its effects. This response is non-specific, and its basic pattern is the same, irrespective of the nature of the original stimulus. Quantitatively, however, the reaction may vary with the intensity of the stimulation and the tissue concerned. One component of the reaction may also predominate at the expense of others, but all are present in different proportions.

---

* Some of the work summarised here was supported by the Walter P. Murphy Foundation and by a U.S. Public Health Service grant.

To keep the concept of inflammation clear it is also essential to recognise the distinction between the inflammatory reaction and its possible sequelæ—e.g., necrosis, suppuration, formation of granulation tissue, and sclerosis.

CHEMICAL MEDIATION OF TISSUE REACTIONS

Systematic study of the mechanism of tissue reactions began about thirty years ago with the work of Krogh (1929), Ebbecke (1923), and Lewis (1927), who showed that certain types of response to mechanical, thermal, and chemical stimuli are associated with the local release of a substance (" H-substance ") similar to histamine. The introduction of histamine into the tissues was shown to reproduce some of the features of the response. Later work (Dragstedt 1941, Feldberg 1941, Ungar 1937) has shown that histamine is also involved in the anaphylactic and anaphylactoid reactions and may play a part in the allergic or hyperergic type of inflammation. These early studies introduced the concept of a biochemical process underlying the inflammatory reaction. The concept subsequently gained wide acceptance. Opinions conflict only about the relative importance of the substances involved and the nature of the reactions by which they are released.

It soon became apparent that histamine alone cannot be responsible for all the components of the basic inflammatory response; and, in addition to the H-substance, liberation of a less diffusible " H-colloid " (Krogh 1929) or of a " slow-reacting substance " (Feldberg 1941) was postulated under certain conditions of tissue stimulation. In recent years polypeptides have been extracted from tissues or from inflammatory exudates. These, when injected into normal tissue, reproduced certain features of the inflammatory reaction (Duthie and Chain 1939, Menkin 1940a, Rocha e Silva et al. 1949, Spector 1951). Although the causal relationship between these peptides and inflammation is not clearly established, the reported observations suggest that one of the intermediate steps between tissue stimulation and inflammation is the breakdown of some protein molecules.

There is also evidence that histamine may be released as a result of protein breakdown. Although final proof of this proteolytic theory is still lacking, there is strong circumstantial evidence in its favour: (1) proteolytic enzymes can liberate histamine from cells in vitro as well as in vivo (Rocha e Silva 1946); (2) proteolytic activity can be detected in blood and tissues under conditions in which histamine is liberated (Ungar 1937, 1944, 1947a, Ungar and Mist 1949); and (3) agents which inhibit proteolytic activity also inhibit the release of histamine (Ungar 1944, Ungar and Damgaard 1951, Ungar et al. 1951a). The so-called protease inhibitors, however, do not prevent the release of histamine in vitro (McIntire et al. 1950).

An alternative mechanism has been proposed for the release of histamine (McIntire et al. 1951). It is based on the observation that histamine can be liberated in vitro and in vivo by several comparatively simple amines or more complex alkaloids (McIntire et al. 1951, MacIntosh and Paton 1949, Feldberg and Paton 1951). This was interpreted as the competitive displacement of histamine from a loose combination. However, one cannot exclude the possibility that these "histamine liberators" act through a proteolytic enzyme system, since this mechanism is compatible with the kinetics of the reaction when it takes place in the presence of an enzyme inhibitor (McIntire et al. 1951.) Preliminary experiments show that histamine-liberating amines —e.g., octadecylamine—and alkaloids—e.g., morphine—do activate profibrinolysin when added to guineapig serum in vitro.

FIBRINOLYTIC SYSTEM IN INFLAMMATION

Evidence has been accumulating for some years that the so-called fibrinolytic system may be involved in shock and inflammation (Macfarlane and Biggs 1948). This system includes a precursor, profibrinolysin, which, when acted on by a fibrinokinase, is converted into an active protease, fibrinolysin. The enzyme thus released is inactivated by an inhibitor, antifibrinolysin.†

Profibrinolysin is a normal constituent of blood-serum (Christensen and MacLeod 1945, Loomis et al. 1947). The first kinases known to promote its conversion into fibrinolysin were the bacterial toxins streptokinase and staphylokinase (Garner and Tillett 1934, Milstone 1941). The rôle of these bacteriofibrinokinases is clearly limited to bacterial infection by strains able to produce the toxin. The range of activity of cytofibrinokinase is much wider; this kinase is present in various tissue cells and is liberated when the cells are injured (Astrup and Permin 1948). It is non-diffusible and can be recovered from the microsomic layer of cell debris (Tagnon and Palade 1950). A third type of kinase, serofibrinokinase, is present in serum in an inactive form, which is activated by the antigen-antibody reaction as well as by certain anaphylactoid stimuli. The kinase thus activated converts profibrinolysin into fibrinolysin (Ungar and Mist 1949, Geiger 1952).

The kinetics of profibrinolysin activation differ according to the type of kinase: activation is slow and progressive with bacteriokinases and cytokinase (Milstone 1941, Astrup and Permin 1948), and sudden and explosive with serokinase (Ungar and Mist 1949).

Fibrinolysin, formed by the activation of profibrinolysin, is different from other animal proteases (Christensen and MacLeod 1945). In addition to fibrinogen and fibrin, it attacks such usual protease substrates as casein, gelatin, hæmoglobin, &c. Its activity has often been measured by semi-quantitative methods (Loomis et al. 1947, Seegers 1950), but more precise enzymological methods can be used in its study to definite advantage (Christensen and MacLeod 1945, Ungar et al. 1951a).

Inactivation by antifibrinolysin begins as soon as fibrinolysin is released. Antifibrinolysin inactivates not only fibrinolysin but also trypsin, chymotrypsin, the leucoproteases, and probably other proteolytic enzymes (Grob 1946). Its existence in serum was reported by Hildebrandt (1893) and has been widely studied, usually through its inhibitory action on trypsin. There are, however, distinct disadvantages in using trypsin for this study, because this enzyme is not present in blood and there is a considerable difference in the rates of inactivation of trypsin and fibrinolysin (Christensen and MacLeod 1945). *Antifibrinolysin inactivates fibrinolysin much more slowly than trypsin* (Guest et al. 1948). The peculiar kinetic behaviour of the fibrinolysin-antifibrinolysin reaction is a very important point. Recognition of its significance is essential for understanding the whole fibrinolytic mechanism.

In the active interval between the release of fibrinolysin and its inactivation the enzyme is free to act on proteins

---

† The terms fibrinolysin and anti[illegible] are also used sometimes to designate [illegible] tococcal fibrinokinase (Garner and Tillett [illegible] ly at present usually referred to as streptokinase and antistreptokinase (Milstone 1941). To avoid confusion some workers have adopt[illegible] [illegible] term 'fibrinolysin' has been retained for the enzyme by most workers mainly because it was first described under this name by Dastre (1893).

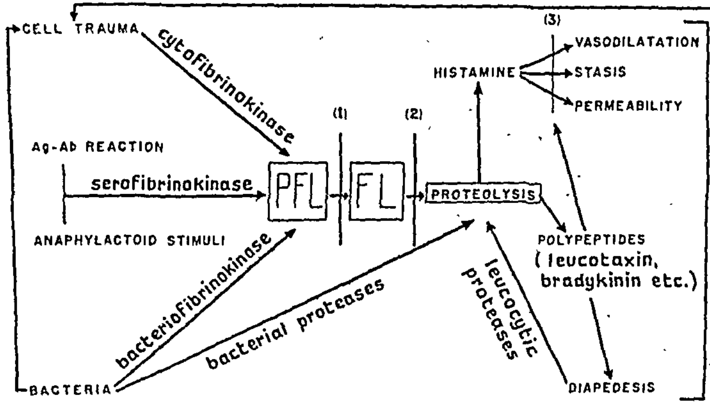

Fig. 1—Fibrinolytic hypothesis of inflammation: PFL, profibrinolysin; FL, fibrinolysin; 1, 2, and 3, points at which mechanism can be blocked.

and to release histamine and other substances, which in turn give rise to the various components of the inflammatory reaction: vasodilatation, increase in capillary permeability, stasis, and diapedesis. Proteases other than fibrinolysin *can no doubt initiate the same process, and* this may happen when tissues are infected by protease-producing bacteria. Leucocytic proteases may also contribute to the proteolytic process when white cells are disintegrating in the inflammatory focus. A vicious circle is established when more and more cells are injured under the influence of capillary stasis and anoxia, and when the cycle is constantly renewed by liberation of cytofibrinokinase. However, the fibrinolytic system is delicately balanced, and in a normal organism inflammation is self-limiting.

The hypothesis of a fibrinolytic mechanism of inflammation is summarised in fig. 1. The validity of this hypothesis can be tested by determining whether there is a correlation between the effects of certain conditions on the fibrinolytic system on the one hand and on the inflammatory reaction on the other. Fig. 1 indicates that, according to the present hypothesis, inflammation can be prevented (1) by blocking the conversion of profibrinolysin into fibrinolysin, (2) by inhibiting fibrinolysin, and (3) by inactivating histamine and other vaso-active substances.

For example, heparin at high concentrations is known to block profibrinolysin activation (Ungar and Mist 1949), as shown in fig. 1, point 1, and it is also known that heparin can prevent certain types of inflammatory reaction, especially *the Arthus phenomenon* (Grégoire 1946).

The action of histamine is inhibited (fig. 1, point 3) by anti-histamine drugs, whose main clinical use is to block allergic inflammation.

Inactivation of fibrinolysin (fig. 1, point 2) seems to take place spontaneously in the fibrinolytic system by antifibrinolysin. However, by virtue of the kinetics of the fibrinolysin-antifibrinolysin reaction there is an "active interval" sufficient to allow fibrinolysin to initiate the inflammatory response. This can be blocked either by an agent which exerts a rapid inhibitory action on fibrinolysin or under conditions which accelerate the inactivation of fibrinolysin by its natural inhibitor. Experimental evidence will now be given to show that both these actions may be exerted by two different types of agents.

FIBRINOLYSIN INHIBITION BY ANTIPHLOGISTIC DRUGS

Salicylates are among the oldest and most widely used antiphlogistics. Recent experimental findings show that sodium salicylate inhibits fibrinolysin in vitro. The inhibition takes place at concentrations similar to the blood level of salicylate required for therapeutic activity (Ungar et al. 1952). This observation prompted a systematic inquiry into a possible correlation between in-vitro inhibition of fibrinolysin and in-vivo antiphlogistic effect.

Table I shows that, for most of the drugs tested, there is a definite correlation between the two effects. Substances which inhibit fibrinolysin in vitro also reduce the Arthus phenomenon and are known to be clinically active in certain types of inflammation (group A). On the other hand, substances which have no demonstrable antiphlogistic activity, although they are structurally related to salicylic acid, were found inactive on fibrinolysin in vitro (group B). The only discrepancy (group C) is shown by drugs which are known to be converted in the body into other substances before exerting their action. It is known that acetylsalicylic acid is converted into salicylic acid (Smith et al. 1946), the dihydroxybenzoic acids (gentisic and γ-resorcylic) into the corresponding quinones (Meyer and Ragan 1948, Ungar et al. 1952), and the two last members of the group into *p*-amino-phenol (Michel et al. 1937).

The foregoing observations are compatible with the possibility that certain antiphlogistic drugs—such as those which owe their action to an *o*-hydroxy group in benzoic acid, the pyrazolone, *p*-aminophenol, and *cinchoninic-acid derivatives—act by inhibiting* fibrinolysin and blocking the fibrinolytic system at point 2 of fig. 1.

ENDOCRINE CONTROL OF INFLAMMATION

The discovery of the striking clinical effects of pituitary adrenocorticotropic hormone (A.C.T.H.) and cortisone (Hench et al. 1949) raised the problem of the mechanism of their action. Failure to explain the clinical effects by either the metabolic action of these hormones or their influence on antibody production led to the concept of a non-specific antiphlogistic action exerted by A.C.T.H. and cortisone (Dougherty and Schnaebeli 1950). Even before the discovery of the clinical effect of these hormones it was known that adrenocortical extracts prevented the increase in capillary permeability induced by tissue *injury* (Menkin 1940b, Ungar 1947b) and inhibited the release of histamine from blood-cells (Ungar 1944). These observations prompted an inquiry into the possibility of an action of the pituitary and adreno-

p-Hydroxybenzoic acid	−	−
Group C:		
Acetylsalicylic acid	−	+
Gentisic (2, 5-dihydroxybenzoic) acid	−	+
γ-Resorcylic (2, 6-dihydroxy-benzoic) acid	−	+
Acetanilide	−	+
Phenacetine (*p*-ethoxyacetanilide)	−	+

* Each drug was tested between the concentrations of 5 × 10^{-4} and 5 × 10^{-3}M.

† Assessed according to clinical action recorded in published reports and tested experimentally on the Arthus phenomenon (Ungar et al. 1951b).

TABLE II—CORRELATION BETWEEN INFLAMMATION AND ANTIFIBRINOLYTIC ACTION OF SERUM IN ANIMALS TREATED WITH VARIOUS HORMONES

—	Antifibrinolysin *	Inflammation †
Control	100	100
A.C.T.H. 15 mg.	124	38
Cortisone 5 mg.	129	21
Deoxycortone acetate 5 mg.	99	91
11-Desoxycortisone 5 mg.	102	81
Deoxycortone acetate 5 mg. eight days	50	164
Thyroid-stimulating hormone 5 mg. four days	26	173
Growth hormone 5 mg. four days	47	162

The figures are percentage values compared to the controls. All the figures are averages of results obtained in groups of 5–20 guineapigs. The probability that the means are not different from the controls is smaller than the conventional limit of 0·05.

* Amount of fibrinolysin inhibited by 1 ml. of serum in 5 min. (Ungar et al. 1951a).

† Measured by the "swelling index" (Ungar et al. 1951b).

cortical hormones on the fibrinolytic system (Ungar and Damgaard 1951). Treatment of laboratory animals with A.C.T.H. or with cortisone did not prevent the conversion of profibrinolysin in their serum. It was found, however, that the serum of animals treated with the hormones inhibited fibrinolysin more quickly than did the serum of untreated animals. This observation led to a systematic investigation of the fibrinolysin-antifibrinolysin reaction in the serum of guineapigs and rats treated with various hormones (Ungar et al. 1951a). Antifibrinolytic activity was determined after five minutes' contact between the serum and the enzyme, thus measuring not the total antifibrinolysin but the rapidly available fraction of it. It is believed that this indicates the rate of the fibrinolysin-antifibrinolysin reaction. Since, however, the kinetics of the reaction are not well known, it is not clear whether a change in the rate is controlled by some catalyst or by the relative concentration of the two reagents. Results of kinetic studies of the fibrinolysin-antifibrinolysin reaction now being made in this laboratory seem to indicate that the rate depends on the presence of accelerating or retarding substances in the serum.

The effect of the same hormones was studied simultaneously in experimental inflammation (anaphylactic arthritis) (Ungar et al. 1951b). The intensity of the reaction was measured as a function of the swelling of the inflamed area. This was done not because it is believed that œdema is the most important component of inflammation but purely for expediency, since swelling is the most easily measurable manifestation of the inflammatory reaction.

Table II summarises some of the results and shows the correlation between antifibrinolytic activity of serum and the modification of the inflammatory reaction. It is seen that both A.C.T.H. and cortisone reduce the swelling and increase antifibrinolytic activity. Deoxycortone acetate and desoxycortisone (Compound S) given in a single injection have no significant effect on the swelling or on antifibrinolysin. Table II also shows that certain hormones (prolonged administration of deoxycortone and pituitary thyroid-stimulating and growth hormones) increase inflammatory œdema beyond control levels, and that the sera of the animals treated with these hormones have a low antifibrinolytic activity.

The observation that the inflammatory response is increased by repeated injections of deoxycortone or of pituitary growth hormone agrees with the findings of Selye (1950, 1951)—i.e., that prolonged administration of either of these substances induces a type of tissue injury similar to allergic inflammation. The theory of diseases of adaptation requires the assumption that when the general adaptation syndrome, operating through A.C.T.H and cortisone (see upper part of fig. 2), is exhausted its place is taken by a mechanism harmful to the organism and operating through the production of growth hormone and 11-desoxysteroids. Recent observations (Ungar et al. 1951a and b) suggest, however, a different sequence of events for this second mechanism (see lower part of fig. 2). Conditions which increase the concentration of circulating thyroid-stimulating hormone of the pituitary—e.g., thyroidectomy and overdosage of thyroxine (Rawson and Money 1949)—decrease antifibrinolytic activity in the serum and increase the inflammatory reaction. This seems to implicate thyroid-stimulating hormone to the same extent as growth hormone.‡ There is also evidence that both these pituitary hormones are still active after adrenalectomy. This indicates that their action is not mediated by the 11-desoxysteroids. Present data suggest rather that the presence of the pituitary gland is necessary to the inflammation-promoting action of deoxycortone.

Fig. 2 summarises the endocrine control of inflammation as it may operate through the fibrinolytic system. A given aggression which elicits an inflammatory response also stimulates the pituitary through either the central nervous system or the metabolites of the tissue reaction. This stimulation sets in motion two opposite mechanisms: (1) release of A.C.T.H. stimulation of the adrenal cortex, which in turn releases Compound F or cortisone; and acceleration of the inactivation of fibrinolysin and inhibition of inflammation (see upper part of fig. 2); and (2) release of growth hormone or thyroid-stimulating hormone, slower inactivation of fibrinolysin, and augmentation of the inflammatory reaction (see lower part of fig. 2).§

The question marks on fig. 2 indicate some of the many problems raised by these observations: are the two endocrine mechanisms set in motion simultaneously, one of them predominating quantitatively, or do they succeed each other in time? Are the endocrine actions

---

‡ Since no pure preparation of either hormone is available, it is impossible to decide, simply by injecting them into animals, whether the effects here described are due to growth hormone, thyroid-stimulating hormone, or a third and unknown substance present as an impurity in the preparations.

§ There is a great deal of evidence (Ungar 1945, 1947b, Ungar and Damgaard 1951, Ungar et al. 1951a and b) that the spleen may play a part in the antiphlogistic action of the pituitary and adrenal cortex: cortisone does not reduce inflammatory œdema and does not accelerate the fibrinolysin-antifibrinolysin reaction in splenectomised animals; and a substance produced by the spleen (splenin A) can reproduce both these effects of cortisone. The spleen and the bone-marrow may also play a part in the inflammation-promoting action of the pituitary hormones through the release of another substance (splenin B). These observations, however, still await confirmation or denial from other laboratories.

different according to the nature of the stress, the inflammation-promoting mechanism resulting from some "special" stress? Can the balance of the two types of pituitary hormones be influenced by functional disturbances of the thyroid or the adrenal cortex?

There is a strong indication that this balance between A.C.T.H. on the one side and thyrotrophic and growth hormones on the other is the main factor in determining whether inflammation is self-limited, as happens in normal organisms, or becomes a self-perpetuating, chronic, or repetitive process.

MEANING OF INFLAMMATION

Inflammation has been considered as a defence mechanism ever since John Hunter suggested that it might serve a useful purpose. Recent evidence lends support to this view by showing that inhibition of the inflammatory response by corticotrophic hormone or cortisone facilitates the penetration of micro-organisms into the blood-stream and their dissemination (Mogabgab and Thomas 1950). However, the introduction of the question of purpose into the problem of inflammation, instead of helping to solve it, tends to confuse the issues. Inflammation is useful when it fulfils what, from a strictly pragmatic point of view, can be called its purpose: fixation of the aggressive agent and, consequently, protection of the rest of the organism. Quite as often, however, inflammation serves no detectable purpose and can even be harmful. Neither of the two mechanisms of endocrine control can therefore be called unreservedly good or bad.

From an objective biological point of view inflammation is the result of a complex chain of biochemical reactions controlled by the endocrine system. Since inflammation is the normal response of animal tissues to environmental changes it definitely has some survival value. It seems, however, that when the same sequence of biochemical reactions occurs at the systemic level, instead of being limited to a tissue, the resulting response, termed the shock syndrome (Moon 1938), is undoubtedly purposeless and harmful. This seems to suggest that the same mechanism can have adaptive value at a local level and no homeostatic significance whatever when it operates at the level of the organism as a whole.

Whatever the biological significance of inflammation, maybe better understanding of its mechanism would mean a considerable advance in our knowledge of disease processes. The hypotheses presented here will be either verified or eliminated by further experimentation. Meanwhile they can be justified if they fulfil the words of Claude Bernard: "Hypotheses and theories, even if mistaken, are useful in leading to discoveries" (Bernard 1865).

THE EMERGENCY OBSTETRICAL SERVICE

A REVIEW OF 489 CASES IN THE MANCHESTER AREA

C. J. DEWHURST
M.B. Manc., M.R.C.O.G.
LECTURER IN OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY OF SHEFFIELD; FORMERLY SENIOR REGISTRAR, ST. MARY'S HOSPITALS, MANCHESTER

It is a tragic event in childbirth when a mother bleeds to death. Fortunately it is a rare event nowadays, the number of maternal deaths from this cause having declined in common with those from other causes. Nevertheless in maternal mortality, hæmorrhage ranks a close second to toxæmia of pregnancy as a cause of loss of life. Moreover, the decrease in the number of deaths from hæmorrhage probably owes more to the efficiency of the blood-transfusion service and to the wider use of obstetric emergency units ("flying squads") than to improved management of the third stage of labour or reduction in its complications.

The good results which have followed extension throughout the country of the flying-squad services have been shown for the Newcastle region by Stabler (1947) and for other centres by Lloyd (1949), Shotton (1949), Shaw (1949a), and others. In the Manchester region, since 1936, the Emergency Maternity Service has been available for complications of the third stage of labour. Between September, 1947, and December, 1950, during which time I was connected with this service, 489 patients were treated. The calls were taken mainly by 12 doctors of registrar status, but sometimes by doctors not normally in the service. It was felt that an analysis of these cases might not only give additional information on the value of the service as at present constituted but would also show how our treatment of the third stage of labour and its complications might be improved, and how deaths from hæmorrhage might be prevented. The present paper comprises the results of this analysis.

COMPOSITION AND SCOPE OF EMERGENCY UNIT

The emergency team consists of a registrar and a sister, who are always readily available. A sufficient number of calls are received weekly for this to be possible. The efficiency of the service is greatly increased if valuable time is not lost searching for personnel to attend the call. This is an argument in favour of a single emergency unit serving a relatively large area, rather than two or more units which would be used much less frequently. In this respect it is important also that equipment is used sufficiently often for the sterility of the contents of the drums to be assured. Two complete sets of equipment are constantly ready, and drums are re-packed and re-sterilised immediately on completion of the case.

A detailed list of requisite articles of equipment has been given previously by Shotten (1949) and will not be repeated here. The materials used by the Manchester unit are almost identical. Any emergency obstetrical procedure can be performed without inconvenience other than that caused by the confined space of many of the patients' homes.

On receipt of a call the registrar on duty speaks to the practitioner or midwife. If the case is suitable, a car is at once loaded while the address is being located on the map. Blood, which is always rhesus-negative group O, is checked by the registrar or sister before setting out. The area served is wide, and calls may be received from thirty miles away or farther. Most of them, however, are to patients within ten miles of the hospital, who can normally be reached without serious loss of time.

Any case of complication of the third stage of labour is accepted and attended. In addition, as table I shows, other conditions where bleeding may be severe are sometimes seen, such as abortion, antepartum hæmorrhage, and secondary postpartum hæmorrhage. An additional duty which the flying squad has performed since 1947 has been to attend eclamptics in their homes, transferring them to hospital only after adequate initial treatment has been given. As has been pointed out by Shaw (1949), it is not part of the flying squad's duties to attend most of the antepartum and intrapartum obstetrical emergencies; such patients are better transported to hospital and dealt with there.

TABLE I—NUMBERS AND TYPES OF CASES TREATED

Type of case	No. of cases
Retained placenta	245
Postpartum hæmorrhage and shock	143
Abortion	33
Eclampsia	23
Antepartum hæmorrhage	9
Secondary postpartum hæmorrhage	9
Other conditions	27
Total	489

Nearly all the calls are for complications of the third stage of labour or of the immediate postpartum period, and it is on such cases that emphasis is laid here.

TREATMENT

Retained Placenta

The practitioner is asked to give his patient intramuscular ergometrine 0·5 mg., if he has not already done so, to limit the amount of bleeding while the squad is on its way. Experience of this over the last three years has seemed to confirm the original impression of Shaw (1949b) that the firm uterine contraction which results prevents further hæmorrhage.

On arrival a rapid history is taken and the patient is examined. Where shock is moderate, the blood-pressure, the pulse-rate, and the patient's general condition will indicate whether blood is needed or not. In cases of extreme shock we have often given a blood-transfusion at once without waiting to read the blood-pressure.

For the transfusion rhesus-negative group-O blood is always used, because the patient's rhesus group is seldom known for certain. If there is time, a direct compatibility test is made before any blood is given, but in a case of great urgency this may be dispensed with. Blood may be given if necessary under pressure.

On abdominal examination it is occasionally evident that the placenta has separated and is lying in the lower uterine segment or in the vagina. It is in this type of case, with the patient shocked by blood-loss and perhaps by repeated attempts at placental expression, that cord traction to deliver the placenta is most valuable, because it permits gentler handling of the uterus. But, as has been emphasised before (Dewhurst and Bevis 1951), this is a dangerous practice unless the operator is *certain* that the placenta has separated and is awaiting delivery, and that the uterus is firmly contracted.

Bleeding has usually ceased either because of the uterine contraction induced by ergometrine or because of the fall in blood-pressure. Sometimes, however, the uterus is full of blood, although there is no continuing external bleeding. The fundus will then be found well above the level of the umbilicus or even as high as the costal margin. In this type of case considerable benefit to the patient results from the gentle expulsion of this retained blood by fundal pressure, and obvious improvement in the patient's condition may be noted before the blood-transfusion could have been responsible, or indeed before the drip has been set up. While the attendants at the confinement are awaiting the arrival of the flying squad, someone must keep a hand constantly on the uterus to detect any rise in the level as the relaxed organ fills with blood. This should be done even when ergometrine has been given.

Attention is next paid to removing the placenta as simply and as safely as possible. The question of whether or not an attempt should be made to express the placenta by abdominal manipulation—usually squeezing and thrusting the uterus downwards—is debatable. Stabler (1947) suggested that one attempt should be made and not repeated. Repeated attempts have probably been made already, from which shock may have resulted. If the patient is extremely shocked, it is probably safer to proceed directly to manual removal. In this series most of the placentæ were removed manually.

The placenta is usually removed under inhalation anæsthesia induced by the patient's own doctor. Latterly thiopentone was used from time to time with good results. As a rule only a very small amount was needed to obtain adequate relaxation. Dangers arising from open fires in the room are also thus avoided.

The time of removal of the placenta is very important. This should be as soon as the patient shows signs of improvement, usually after 15–30 minutes, when $^{1}/_{2}$–1 pint of blood has been given. To wait longer in the hope of getting the patient's blood-pressure much above 80 mm. Hg is undesirable; bleeding is likely to begin again, the blood-pressure will fall again, and all that has been gained may be lost.

I am confident that the sooner the placenta is removed and the patient's blood-pressure comes back permanently towards normal, the better—and the change in management of these cases in recent years in Manchester supports this view. It is a mistake to think that these patients will not stand the anæsthetic while the blood-pressure is still well below 100 mm. Hg. They will do so readily, they will require very little anæsthetic, and they will often be found to be improved when the placenta has been removed, before the anæsthetic has been discontinued. These facts have been stated before (Stabler 1947, Shotten 1949) but they are worth stating again.

After the removal of the placenta, recovery is usually rapid; further active treatment is unnecessary beyond the transfusion of a second pint of blood in some cases.

In a few cases, however, under certain conditions (see below) it is advisable to transfer the patient to hospital for further observation and treatment.

Postpartum Hæmorrhage and Collapse after Delivery of Placenta

As these patients are suffering from blood-loss, transfusion is the most effective treatment. In the straightforward type of case excellent results are obtained from this simple treatment, more than two pints of blood being seldom needed.

The recovery after transfusion of the healthy patient shocked from blood-loss alone is dramatic. Hence, if a rapid response is not obtained to transfusion, a careful assessment of the case must be made lest a more serious abnormality (e.g., rupture or inversion of the uterus) which requires urgent treatment has been overlooked. Even in the absence of such severe accidents as these the patient will be found occasionally to be more shocked than the blood-loss alone would account for. Repeated traumatic attempts to express a retained placenta may be to blame; so also may the injection of pituitary extract. Retained blood—sometimes in large amounts—may be found in the uterus, and should be expelled at once.

These conditions should be remembered as a cause of delay in recovery (see below).

Abortion, Antepartum Hæmorrhage, and Secondary Postpartum Hæmorrhage

The majority of these cases do not require the services of the emergency unit. It is occasionally necessary to resuscitate a patient before she is fit to undertake the journey, and it may even be necessary to transport her to hospital with the blood-drip in place. Rarely will it be possible to deal effectively with any of these complications in the patient's home, and the wisest course is transfer to hospital. More than half the cases of abortion which the squad attended required no preliminary treatment before removal to hospital, and, of course, for only a small fraction of the number of abortions admitted to the hospital were the services of the flying squad ever requested.

Eclampsia

The flying squad has dealt with eclampsia to avoid long journeys with the patient inadequately sedated and to ensure that the patient is attended constantly by medical personnel in an attempt to limit further fits. Doctors requesting admission of an eclamptic patient are asked to give the patient morphine at once and to remain with her until the arrival of the unit. Morphine and paraldehyde have been the drugs mainly used for the initial sedation before transfer of the patient to hospital. If the first injection of morphine has been given by the doctor, a further injection of gr. $^1/_4$ is given on arrival of the squad, followed shortly by paraldehyde either 5–10 ml. intramuscularly or drachms 6 in oil by rectal instillation. Some time later, when the attendant is satisfied that the level of sedation is satisfactory, the patient is removed to hospital in the ambulance. Everything which may be required in the event of a further fit is at hand during the ambulance ride. Magnesium sulphate is sometimes given in the early stages if the blood-pressure is very high; 10 ml. of a 20% solution being injected intravenously. It was rare for the patient to have further fits under this régime.

Obstetric examinations are reduced to a minimum, and no examination per vaginam is made unless the patient is thought to be in labour with the cervix nearing full dilatation. On two occasions, when the patient was in the second stage of labour, she was delivered at home before removal to hospital.

TABLE II—RETAINED PLACENTA

Total no. of cases	245
Placenta :	
Delivered on arrival	15 (*6·1%*)
Removed manually	175 (*71·4%*)
Expressed	55 (*22·4%*)
Shock :	
Present	156 (*63·7%*)
Absent	89 (*36·3%*)
Transfusion	179 (*73·1%*)
Parity :	
1	74 (*30·2%*)
2–5	149 (*60·8%*)
6 +	22 (*8·9%*)
Delivery :	
Normal vertex	219 (*89·3%*)
Forceps	17 (*6·9%*)
Breech, &c.	9 (*3·6%*)
Maternal deaths	2 (*0·8%*)

TABLE III—POSTPARTUM HÆMORRHAGE AND COLLAPSE

Total no. of cases	143
Parity :	
1	54 (*37·7%*)
2–5	82 (*57·3%*)
6 +	7 (*4·9%*)
Delivery :	
Natural forces	115 (*50·4%*)
Forceps	28 (*19·6%*)
Shock present	104 (*72·7%*)
Shock present but delayed	40 (*27·9%*)
Transfused	107 (*74·8%*)
Inversion of uterus	3 (*2·1%*)
Rupture of uterus	1 (*0·7%*)
Maternal deaths	5 (*3·5%*)

DISCUSSION

The value of the emergency obstetrical service is evident from examination of the results obtained (tables II and III). As will be seen from table II, of 245 patients with retained placenta 156 were shocked, many severely so. The placenta was successfully removed manually in 175 cases; 179 patients received a blood-transfusion with great benefit. When it is remembered that some of these patients were situated twenty, thirty, or more miles from hospital, 2 maternal deaths does not seem a high figure. The alternative treatment of transfer of these patients to hospital—even after transfusion—would almost certainly have led to a much higher mortality.

Two comments must be made on table II which reflect upon the general conduct of the third stage of labour. The first is to note with approval that in a third of the cases blood-transfusion was not required, and the general condition of the patient had not been allowed to suffer despite the third-stage abnormality. Probably this proportion can be increased further. Bleeding during the third stage before any other sign of placental separation is apparent often indicates the presence of an abnormality. If the placenta is not separating normally and cannot be expressed with one attempt, and manual removal is deemed inadvisable, the attendant should try to prevent shock by refraining from any further expression, to limit the blood-loss by giving ergometrine, and to control the fundus until assistance has arrived.

The second comment is on the fact that the flying squad was called to 17 patients with retained placenta after the practitioner had delivered the patient with forceps. It is surely a criticism of our medical teaching that doctors will embark on a forceps extraction but will not undertake manual removal of the placenta while the patient is still anæsthetised. As Stabler (1947) has pointed out, this is no doubt due to the old teaching that manual removal is the most dangerous operation in obstetrics. He emphasises that it is a life-saving operation and is easier and less dangerous than a forceps extraction. The flying squad once travelled thirty miles to find a woman, extremely shocked, who had been delivered with forceps two hours previously; she required a blood-transfusion, a second anæsthetic, and a manual removal of the placenta, which could have been done safely and easily very soon after the delivery when it became apparent that the placenta was not coming away.

The first of the 2 maternal deaths in this group illustrates this point.

Case 1.—A primigravida had been 48 hours in the first stage of labour. After 10 hours in the second stage she was given 0·5 ml. of 'Pituitrin.' Delivery did not follow; so she was delivered with low forceps under chloroform anæsthesia. After a further $2^{1}/_{4}$ hours the placenta was still not delivered and the flying squad was called. Resuscitation was started, followed by manual removal of the placenta $4^{1}/_{2}$ hours after delivery. The patient's general condition then seemed good, and she was left, only for the emergency service to be recalled $1^{1}/_{2}$ hours later because of a deterioration in her condition. Despite further treatment she died 4 hours later.

There are, of course, other factors here which no doubt contributed to a fatal result apart from the failure to remove the placenta until $4^{1}/_{2}$ hours after delivery. The dangers of whole-pituitary extract are discussed below. Cases 1 and 2 indicate that recovery is not always the rule, despite resuscitation and successful removal of the placenta.

The second death also shows how serious is such hæmorrhage in the woman who has borne many children.

Case 2.—A 9-para was delivered easily and normally. After $1^{1}/_{4}$ hours, as the placenta had still not separated, she was given 5 units of 'Pitocin.' She became shocked almost at once. The flying squad arrived $2^{1}/_{2}$ hours after delivery, to find the patient in extreme shock. She was given blood, and the placenta was removed manually. After 6 hours her blood-pressure was still only 60 mm. Hg, and after 8 hours she had improved to 100/60 mm. Hg, and shortly afterwards she was left in the charge of her own doctor and midwife. The improvement, however, was not maintained, and she died 12 hours later.

It has not been the practice to transfer patients to hospital after the placenta has been removed. Of 245 patients fewer than 10 have been moved. It can be argued, however, that the lives of both of these patients who died might have been saved if they had been transferred to hospital shortly after the improvement became established. Probably transfer is occasionally desirable—for example, where recovery is slow, or where two anæsthetics have been given, or where the patient has borne many children, or where supervision is impossible at home. The possible need for further treatment in such cases should be remembered.

In describing the routine treatment of postpartum hæmorrhage the comment was made that the recovery of these patients was often dramatic. And yet, despite this, 5 mothers died in this group, 4 of them from hæmorrhage alone (table III).

The danger of overlooking a uterine inversion or rupture has already been mentioned. There were 3 cases of uterine inversion, in 2 of which the diagnosis was confirmed on a routine vaginal examination as soon as it was seen that the patient was not improving satisfactorily from the transfusion. The diagnosis of this abnormality is difficult on abdominal examination alone if the inversion is incomplete, but it should be recognised at once if a vaginal examination is made. In all 3 cases, after preliminary resuscitation, the uterus was successfully replaced, in 2 cases by the hydrostatic method (O'Sullivan 1945) and in the 3rd manually. The patients were transferred to hospital afterwards, and each made an uneventful recovery. The cases have been described in greater detail elsewhere (Dewhurst and Bevis 1951).

One case of uterine rupture occurred which forms the first maternal death in this group.

Case 3.—A primipara, aged 35, collapsed towards the end of the second stage of labour. The delivery of the child was normal, and the placenta was expelled normally. Bleeding up to two pints took place during the third stage. Despite blood-transfusion from the flying squad there was no improvement, and a rapid examination per vaginam disclosed a rupture in the posterior wall of the lower uterine segment. The patient's general condition was so poor that she could not be moved for this to be dealt with, and she died shortly afterwards.

Mention has already been made of the dangers of pituitary extract. Of 140 cases of postpartum hæmorrhage crude pituitary extract was given in 28. These patients were among the most shocked of all. There can be little doubt that the injection of whole-pituitary extract to a patient suffering from blood-loss is dangerous. Cardiac irregularities and blood-pressure effects which might follow its injection in a healthy patient are far more serious if they occur in a patient already suffering from blood-loss. This effect cannot be entirely prevented by using purified oxytocic factor, especially if this drug is given intravenously. Intravenous or intramuscular ergometrine is just as effective and far safer.

What has been said previously about the relaxed uterus filling up with blood is no less important here, and the value of expressing the blood is equally evident. The presence of a relatively small amount of blood distending the uterus seems to have a greater effect on the condition of the patient than a similar amount lost externally. Just as the uterus with the placenta retained can fill with blood while the attendants are waiting for the flying squad, so it can fill up even after the third stage is complete. This type of postpartum collapse is most distressing because it is the most easily preventable. In 40 out of the 104 patients, more than half an hour, and sometimes many hours, had elapsed after the *completion* of the third stage before the patient was seen to be in poor condition. Blood had been allowed to accumulate in the uterus, and the level of the fundus had risen unnoticed. As no bleeding was seen externally, no abnormality was suspected; either the fundus was not palpated or, if it was, the significance of the rise in the level was not recognised. It is sufficient only to palpate the uterus from the time following delivery to prevent this type of delayed bleeding and collapse. Should the level be rising, the retained blood should be gently expelled by fundal pressure to allow the uterus to contract vigorously on the empty cavity. Blood allowed to accumulate slowly will effectively prevent this contraction and permit further bleeding. Case 4 shows what disastrous effects this can have.

Case 4.—A 2-para was delivered normally at term. The placenta did not separate, and there was some bleeding; so her doctor removed the placenta manually. Afterwards pituitrin 5 units and ergometrine 0·5 mg. were given intramuscularly, and the patient was thought to be well. Two hours later, however, she was found to be collapsed, and the flying squad was summoned. Despite resuscitation and expulsion of the retained blood in her uterus the patient was too far gone, and died in $1^{1}/_{2}$ hours.

The third maternal death took place in almost exactly similar circumstances in a primipara.

The increased liability to complications of the third stage of labour, when the patient has been delivered with forceps or by other means under general anæsthesia, is obvious from an examination of these figures. 28 patients were delivered with forceps or by breech extraction in this way—an incidence of nearly 20%, which is a very high figure in general practice. It is necessary to add that, when the patient has been delivered under general anæsthesia, precautions are required to overcome the uterine atony and postpartum hæmorrhage which is likely to take place. How effective is the use of ergometrine given when the body of the child is being delivered has been shown by Shaw (1949b).

The last 2 maternal deaths in this group illustrate again the greatly increased danger of postpartum hæmorrhage in the multipara who has borne many children. What has been said about the rapid recovery from hæmorrhage of the healthy patient does not apply to the patient whose general condition before labour is poor.

Many multiparous patients, of course, fall into this group. Gross deficiencies in diet may produce a dangerous state of chronic anæmia, which may be very difficult to detect. Hæmoglobin percentages of 40 or lower are not uncommon in the Manchester area. When postpartum hæmorrhage occurs in these patients, their lives are in jeopardy; death may be too rapid for treatment even to be started.

Case 5.—A 5-para was booked by a midwife a few days before term. She had received no antenatal care because she had travelled round the country throughout her pregnancy. The midwife, recognising her poor state of health, arranged for her to attend a clinic for advice. Labour began, however, before this was done; delivery was rapid, and the patient began to bleed as soon as the baby was born. The placenta was expressed, but heavy bleeding continued. The patient at once became extremely shocked, and died before the arrival of the flying squad, although the delivery took place not more than a mile from the hospital.

Case 6.—A 10-para bled profusely after a premature delivery. Efforts to preserve her life before the arrival of the squad were of no avail, and she died before it could reach her.

These 2 deaths took place in the group of only 7 patients whose parity was more than 5. It is hard to overemphasise the dangers of postpartum hæmorrhage in this type of patient. In all, there were only 27 patients in both groups who had had more than 5 children, and in this small number 3 maternal deaths took place. These facts speak for themselves.

One last type of dangerous patient must be mentioned—namely, the patient who has previously had an abnormality of the third stage of labour. It has been quite common among the cases described here to encounter patients with retained placenta or postpartum hæmorrhage who have had the same complication in a previous pregnancy. When the third stage of labour has once been abnormal in this manner, there is an increased likelihood of recurrence of the abnormality, and it is inadvisable for these patients to be confined outside hospital if this can be avoided.

There is no need to discuss here the cases of abortion and of antepartum and postpartum hæmorrhage. All the patients were transferred to hospital and treated there successfully, without mortality.

Discussion of the subsequent treatment of the cases of eclampsia is not within the scope of this paper, and results will only be given briefly. Four patients ultimately died: 1 from subarachnoid hæmorrhage which was finally decided to have been the primary lesion, the patient not therefore being properly included in these figures; 1 had a cerebral hæmorrhage in the region of the brain stem; 1 had extensive hepatic necrosis and pituitary hæmorrhage; and the 4th had hepatic necrosis with evidence of old chronic pyelonephritis. Although these figures are not good, it is unlikely that they would have been better had the flying squad not attended the patients. It is thought that this is a development of the flying squad which could, with benefit, be put to more widespread use. The excellent results of Dewar and Morris (1947) in Scotland are good evidence of the value of this form of treatment.

Miscellaneous Conditions

Little need be said about this group, which includes such cases as hæmorrhage at cæsarean section done in a nursing-home, 1 case of blood-loss into a large vaginal hæmatoma, 1 ectopic pregnancy, several cases of menopausal bleeding, and even 1 hæmorrhage following tonsillectomy.

CONCLUSIONS

Hæmorrhage in childbirth still constitutes a serious threat to the life of the patient. So long as domiciliary midwifery continues, the need will arise for the treatment of patients bleeding in their own homes. A method of dealing with these emergencies by an obstetrical flying squad staffed at the registrar/senior-registrar level is outlined in this paper. It is submitted that the results obtained provide additional evidence of the value of this type of service and demonstrate that treatment without the routine transfer of a shocked patient to hospital is satisfactory. It is important to the efficiency of the emergency unit that the personnel on duty be immediately available at all times.

If the services of the emergency unit are required, the attendants at the case have an important duty to perform in preserving the patient's general condition while the unit is on its way. To do this, simple measures only are indicated—the prevention of further bleeding by the use of ergometrine, the control of the fundus, and simple measures for the treatment of shock. Repeated attempts at placental expression, and permitting the relaxed uterus to fill up with blood, will increase the degree of shock present; so also will the use of whole-pituitary extract, the use of which is to be deprecated at all times.

The value of blood-transfusion for the patient suffering from blood-loss needs no emphasis. If blood is given to a patient with a retained placenta, the placenta is best removed at an early stage as soon as the patient's condition begins to improve. When a transfusion is given to a patient suffering from postpartum hæmorrhage, if rapid improvement in the patient's condition is not seen, the possibility should be remembered of a further complication which may have been overlooked, such as uterine inversion or rupture.

It does not seem to be sufficiently realised that there is an increased incidence of complications of the third stage of labour when the patient is delivered under general anæsthesia. The services of the flying squad are still requested for retained placenta after the patient has been delivered with forceps. It must be concluded that practitioners, prepared to embark on a forceps extraction, are not all willing to carry out a manual removal of the placenta. This is a simple procedure with which the practitioner should be familiar. The evidence in this report of 175 manual removals indicates that this is not the difficult and dangerous procedure it was formerly believed.

There are some patients in whom the risk of hæmorrhage is increased, making delivery outside hospital dangerous. In this category are those patients who have previously had an abnormality of the third stage of labour, perhaps with a blood-transfusion and a manual removal of placenta. Similarly, multiparæ with many previous pregnancies are often in considerable danger, particularly so if the dangerous state of anæmia so common in this class of patient is present. It is carrying obstetric practice beyond the bounds of safety to confine these dangerous patients at home.

Although most of these patients can be treated completely at home, a few of them should be transferred to hospital after treatment for further observation.

One last point may be emphasised. With the maternal mortality-rate standing at less than 1 per 1000 live births, death of the mother is no longer an adequate yardstick from which to judge the safety of our obstetric practice. Many of the patients mentioned here were near to death—so near in fact as to cause the gravest concern to even the most experienced of the flying squad. There is a natural tendency to recall fatal cases and to forget the others. We should remember them, and profit by the lessons they teach.

SUMMARY

The results are presented of 489 cases treated by the Manchester Emergency Maternity Unit from September, 1947, to December, 1950.

Most of the calls were to cases of retained placenta or of postpartum hæmorrhage, which together totalled

388. In these two groups there were 7 maternal deaths.

The routine methods of treatment used by the Emergency Unit are outlined, and the difficulties and dangers likely to be encountered in the two main classes of patient are discussed.

The maternal deaths are analysed in an attempt to show how similar deaths can be avoided.

My thanks are due to my colleagues on the flying-squad staff of St. Mary's Hospitals, Manchester, who have treated so many of these patients, and also to the nursing staff who have given such able assistance at all times. In particular, I would like to thank Miss C. B. Gott, S.R.N., S.C.M., for assistance in the preparation of these figures. Prof. C. Scott Russell has given me much help in the writing of this paper, and I am indebted to the board of St. Mary's Hospitals, Manchester, for permission to publish these results.

THE SURGICAL TREATMENT OF MALIGNANT RECTAL POLYPS

H. E. LOCKHART-MUMMERY
M.Chir. Camb., F.R.C.S.
SURGEON, ST. MARK'S HOSPITAL, LONDON

With notes on their pathology by

CUTHBERT E. DUKES
O.B.E., M.D. Edin., F.R.C.S., D.P.H.
PATHOLOGIST AND DIRECTOR, RESEARCH LABORATORY, ST. MARK'S HOSPITAL

As is well known, benign epithelial tumours of the mucosa of the large bowel are frequent precursors of cancer. From this it follows that they require treatment, whether or not they are causing symptoms. The majority of such tumours are in the rectum or lower pelvic colon and can usually be seen and removed through a sigmoidoscope, the method of removal depending on the site and the presence or absence of a stalk. For tumours higher in the colon laparotomy and colotomy are commonly used.

All tumours removed in this way should be examined microscopically. If the polyp appeared clinically to be benign, and this is confirmed by the microscopical examination, further treatment will probably not be required. Sometimes, however, though the polyp appeared to be benign, microscopy reveals malignancy. The surgeon is then faced with a difficult decision: can he rely on the removal by local excision, or should he advise excision of the rectum and its field of lymphatic drainage? This problem would be simpler if he could be certain that local recurrence in the bowel would precede dissemination: then a policy of "watch and wait" could safely be advised. But there is doubt as to whether lymphatic metastasis has already taken place, or may do so in the absence of local recurrence or before the latter can be detected. In short, delay may deprive the patient of his only hope of permanent cure.

The purpose of this paper is to try to give some guidance to surgeons faced with the unexpected discovery of carcinoma in a pedunculated rectal tumour which appeared clinically benign and was removed by local excision. Through the courtesy of our colleagues we have had access to all their cases, and we review here a series of such cases treated and carefully followed up at St. Mark's Hospital.

Pathology of Malignant Rectal Polyps

The significance of the discovery of malignancy in a rectal polyp varies greatly according to the extent of the carcinoma and its histological grade of malignancy. To show the importance of the extent of spread, we illustrate in figs. 1–6 the different phases in the evolution of a malignant polyp:

Fig. 1 represents a simple non-malignant pedunculated adenoma in a quiescent state.

In fig. 2 several zones of more active epithelial proliferation, still of a non-malignant character, are represented by darker outlines to some of the mucus-secreting glands.

A further stage in development is represented in fig. 3, in which microscopic foci of carcinoma are represented by black spots. This may be described as "carcinoma in situ"—i.e., the initial stage of malignancy when there is not yet any evidence of infiltration or invasion. Since there is often an element of doubt about the malignancy of a lesion described as "carcinoma in situ," these have not been classified as cancer cases but only as doubtful or suspicious lesions.

The further growth and fusion of foci of "carcinoma in situ" results in a larger lesion, which now is definitely malignant though still almost completely confined to the region of the mucosa. We have illustrated this in fig. 4 as "focal" carcinoma.

When there is evidence of further spread into the stroma of the polyp or into the submucosa of the bowel we describe this as "invasive" carcinoma, which may be further subdivided into cases in which there appears to be an ample free margin below (fig. 5) and those in which there is no apparent free margin (fig. 6).

The histological grading of malignant tumours is now a routine procedure in the examination and classification of many varieties of cancer. The system which has been in use at St. Mark's Hospital for many years is to divide malignant tumours on the basis of the degree of differentiation of the neoplastic cells into "low," "average," and "high" grades of malignancy. A histological classification on similar lines is adopted by most pathologists when reporting on adenocarcinomata. For the grading system in use at St. Mark's Hospital see Gabriel (1948).

Material

In 1933–49 about 2500 cases of rectal cancer were treated surgically at St. Mark's Hospital—47 of them by what was described as local excision. The term

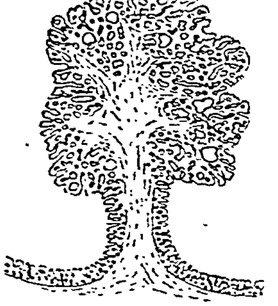

Fig. 1—Mucus-secreting adenoma.

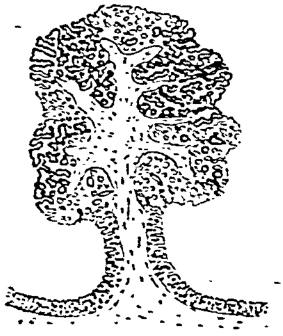

Fig. 2—Proliferation in adenoma.

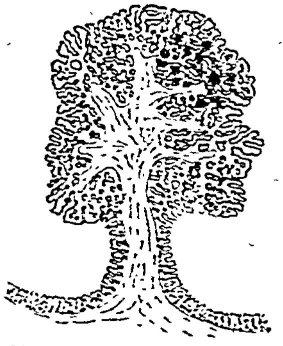

Fig. 3—Carcinoma "in situ."

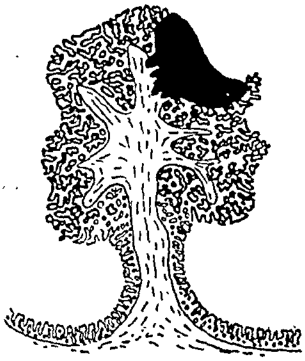

Fig. 4—" Focal " carcinoma.

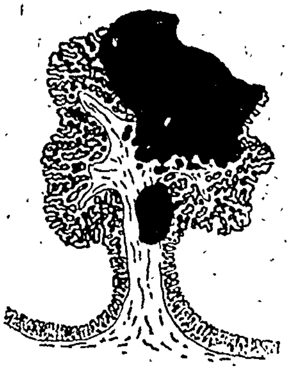

Fig. 5—" Invasive " carcinoma with free margin.

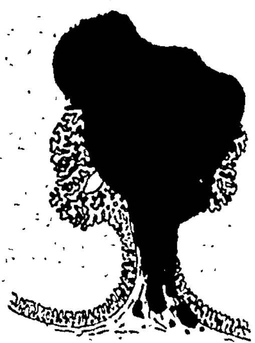

Fig. 6—" Invasive " carcinoma without free margin.

" local excision " has been used to describe any operation in which only the tumour itself was removed, sometimes perhaps with a cuff of surrounding tissue, but with no attempt to remove lymph-glands ; and any tumour in which definite malignancy was found has always been classified as cancer in the records and has thus been available for analysis. These 47 tumours were all malignant, in whole or in part, and the series does not include any tumour of doubtful malignancy or " carcinoma in situ " only.

The tumours varied greatly in size and shape. Some were pedunculated polyps ; others were small semi-pedunculated villous tumours ; others again were small nodular tumours. Most of them were clinically benign tumours in which the malignancy was only discovered on microscopy, but in others the malignancy was known or suspected before treatment was undertaken. These latter were mostly small mobile tumours in which it was felt that local excision might well be curative. It seemed to us that the inclusion of these latter cases was justified because, although malignancy was known or suspected, the method of treatment was that normally applied to a benign tumour.

These 47 tumours were all solitary, arising from the mucosa of the rectum, and were all treated by local excision only ; but we found that during the period under review 18 other tumours of a closely similar character had been treated for various reasons by more radical measures—e.g., combined excision, perineal excision, and restorative resection. In these 18 cases the lymph-glands were also removed, and the pathological reports on these cases have revealed how far the disease had spread. We found it instructive to compare these cases with the 47 treated by local excision, because, apart from the operation performed, the two series were in all respects comparable.

All these tumours—both the 47 removed by local excision and the 18 removed by radical excision—have been reviewed and classified as " focal " or " invasive " and according to their grade of malignancy. We have also attempted to decide, in the cases treated by local excision, whether that excision had apparently been clear of tumour tissue or not—i.e., whether there was an " apparent free margin " or only a " doubtful free margin."

The method of removal varied. Most of the pedunculated polyps were removed with the diathermy snare, whereas the villous tumours and those in which malignancy was clinically suspected were removed by an excision through the full thickness of the bowel wall.

Results

IN " FOCAL " CARCINOMA

(See figs. 4 and 7)

The end-results of treatment of early rectal cancer vary greatly with the stage of development of the disease. In the cases classified as " focal " carcinoma—i.e., carcinoma limited to the mucosa—the results of local excision were completely satisfactory. There were 17 such tumours among the 47 removed by local excision. One patient died from heart-disease four months after operation, but the other 16 are all alive, with no sign of recurrence. The period of observation has varied, but 14 patients have been under observation for more than three years, and 8 for more than five years. One of the 16 patients developed another polyp in another part of the rectum after eight years ; this also showed focal carcinoma on section, but he has remained well since his second operation.

All these 17 cases of focal carcinoma were classified as being of low or average grade of malignancy. It is not surprising that there was no example of high-grade malignancy in this group, because it is well known that undifferentiated or anaplastic carcinomas of the rectum grow rapidly and so would pass quickly from the stage of focal to that

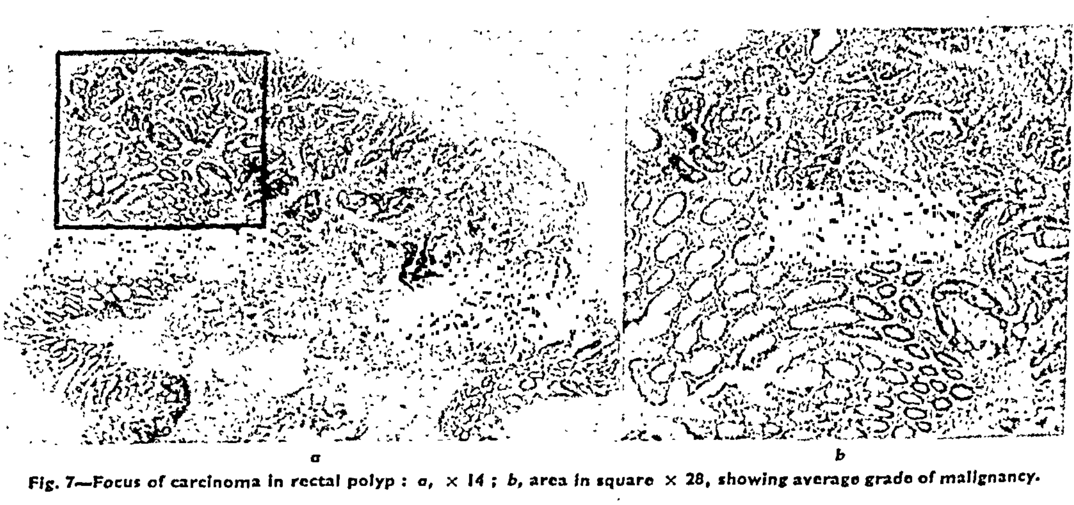

Fig. 7—Focus of carcinoma in rectal polyp : a, × 14 ; b, area in square × 28, showing average grade of malignancy.

of invasive carcinoma. If a carcinoma of high-grade malignancy were found to be still at the stage which we have described as focal, we are by no means sure that it would be safe to rely on local excision alone. So we may sum up our experience of focal carcinoma by saying that local excision certainly seems to be adequate for tumours classified as of low or average malignancy, but we doubt if this would be adequate for undifferentiated carcinomas classified as of a high grade of malignancy, which we think should always be treated radically.

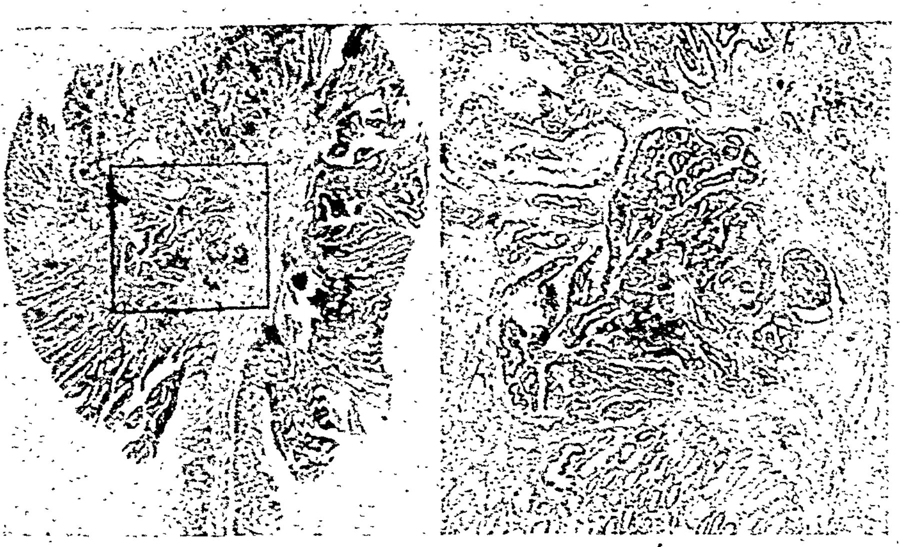

Fig. 8—Early stage of invasive carcinoma arising in pedunculated adenoma: *a*, × 5; *b*, area in square × 16.

IN "INVASIVE" CARCINOMA

(See figs. 5, 6, and 8)

It is in these cases that the grade of malignancy is of special importance in relation to prognosis after local excision. We therefore present the results according to their histological grading and compare them with the findings in the 18 similar tumours treated by radical excision, all of which were considered to be "invasive."

Tumours of Low-grade Malignancy

Of the "invasive" tumours in the series removed by local excision, 7 were considered to be of low-grade malignancy.

One patient had previously had a malignant polyp removed by snare at another hospital, and was referred to St. Mark's for opinion. As the polyp had shown complete replacement by low-grade adenocarcinoma, and had been at a sufficiently high level for a restorative operation, this was done; careful microscopy of the specimen failed to show any residual malignant cells, either at the primary site or in the glands.

The 6 other patients were treated primarily at St. Mark's and have all remained well: 2 for five years, 3 for three years, and 1 for two years.

In 4 of these cases there was an apparent free margin of normal tissue round the tumour, even though the growth had extended into the submucosa of the bowel wall; but in the 2 others there was little if any free margin, yet these patients also are free from evidence of disease two years and three years from the time of treatment. This period of observation is too short for final conclusions, because the natural development of low-grade tumours should be measured in years rather than in months, but it is encouraging that there has so far been no evidence of recurrence or metastasis.

The question of unsuspected metastasis naturally arises here, and in this connection it is instructive to examine the extent of spread in the 18 similar cases of rectal cancer which had been treated by radical excision, 14 of which were considered to be of low-grade malignancy. Examination of the operation specimens showed, in each of these 14 cases, that the growth had not extended beyond the rectum (A cases) and there were no lymphatic metastases.

Tumours of High-grade Malignancy

Of the 47 cases, 3 were classified as of high-grade malignancy, and recurrence took place in each of them.

One of these 3 patients was found to have local induration three months after removal of the polyp. Combined excision was undertaken without delay, and one gland was found to have been replaced by carcinoma; this patient is alive four years later.

The second patient was found, six months after removal of the polyp, to have a small nodule at the previous site. Again combined excision was advised, but it was refused for a further six months, by which time nine glands were found to be involved, though the local manifestations were still slight (see fig. 9). The patient died of metastases six months later, eighteen months after the local excision.

The third case is of particular interest in that on sigmoidoscopy the patient was found to be normal five months after a malignant polyp had been removed. When he was re-examined three months later, a small malignant ulcer was seen at the previous site, and a combined excision was undertaken. The operation specimen showed that five glands were by then involved. The patient died of chest complications a few days after the operation.

A carcinoma of high-grade malignancy was found in only 1 of the 18 similar cases treated by radical excision:

A woman, aged 42, under the care of Mr. Naunton Morgan, complained of rectal bleeding. After several negative X-ray and sigmoidoscopic examinations a polyp was finally seen 18 cm. from the anus, and laparotomy was advised. The colon was opened with a view to local excision of the tumour; but, as it felt hard in one part, the bowel was closed and resection with primary anastomosis was done instead. The operation specimen showed a pedunculated polyp partly replaced by carcinoma of high-grade malignancy invading the stalk, and four lymph-glands contained metastases (C2 case).

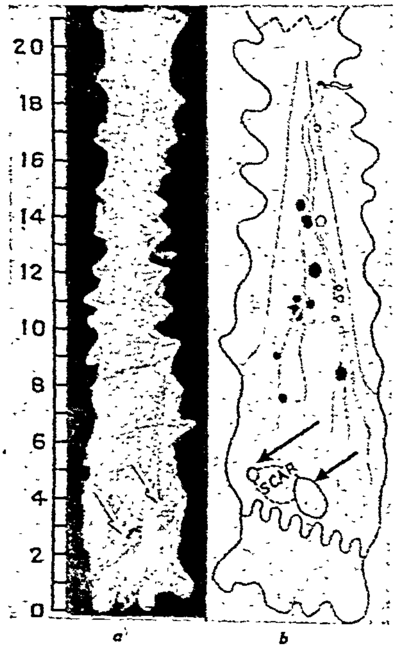

Fig. 9—Recurrence after local removal of rectal polyp containing carcinoma of high-grade malignancy: *a*, operation specimen obtained from synchronous combined excision by Mr. E. T. C. Milligan a year after local removal of polyp; *b*, sites of lymphatic metastases. Arrows indicate sites of recurrence. (Scale in inches.)

It is apparent from these 4 cases that in these tumours of high-grade malignancy lymphatic metastasis occurs early, and that, though local recurrence is likely, extrarectal lymphatic spread may precede any local manifestation.

Tumours of Average-grade Malignancy

These form the largest single group in the series removed by local excision, 20 of the 47 tumours being so classified. Only 6 of the patients have remained well, 4 having been under observation for five years, 1 for six years, and 1 for nine years; 5 others have died from unrelated causes, 4 of them within two years of treatment, but 1 after four years, during which there was no evidence of recurrence.

No fewer than 9, or nearly half, have had further disease. In 2 of them we are ignorant about the first manifestation of recurrence: 1 died of rectal cancer two and a half years after treatment; and the other now, five years after treatment, is reported to have an inoperable rectal growth. Of the other 7 patients 4 showed a localised nodule at the site of former excision as the first sign of recurrence two months, five months, thirteen months, and three years after treatment. They were all treated by combined excision, and in 1 of them a nearby lymph-gland contained a metastasis, though the local recurrence in this case was confined to the mucosa. In the 3 others lymphatic metastasis was the *first* sign of recurrence. In 2 this was in the inguinal glands, the primary having been at the ano-rectal junction, whereas in the 3rd the glands in the mesorectum became palpable through the posterior rectal wall. In none of these 3 cases was there clinically detectable recurrence at the primary site.

Of the 18 tumours removed by radical excision, only 3 were of average-grade malignancy. In 1 of these the malignant change was confined to the pedunculated tumour, but in the 2 others it had extended to the muscle coat, and in 1 of these a nearby gland contained a metastasis. Thus it is apparent that in these tumours of average-grade malignancy early metastasis is not uncommon, even though the tumour may be small and still pedunculated.

It is in the further analysis of this group of cases that we believe the assessment of the margin of clearance may be of value. Excluding the patients who died from unrelated causes, we found that of the 5 cases with an "apparent free margin" only 1 recurred, whereas of the 10 cases with a "doubtful free margin" 8 recurred. Undoubtedly detailed information about the margin of free tissue round a tumour is likely to be of considerable help to the surgeon in deciding future treatment.

Discussion

The discovery of a small unsuspected focus of malignancy in a rectal polyp is not rare, but the literature reveals considerable difference of opinion as to what is the best treatment. Bacon et al. (1951) say that, if definite malignancy is found in a benign tumour, even if the change is only "in situ," a radical excision should be done forthwith. Swinton (1948) reports 22 cases with "early malignant change" treated by local excision and followed up for seven years without recurrence, and is therefore more conservative in his attitude towards treatment. McLanahan et al. (1949) subdivide their cases into "non-invasive" and "invasive" tumours, using much the same criteria as set out above, and show that a third of the "invasive" tumours recurred, an incidence very similar to that found by us (see table). Marino (1948) also emphasises the difference between "invasive" and "in-situ" carcinoma, though neither term is defined.

Most of these workers agree on the importance of removing the whole polyp for careful microscopy, an opinion which we fully endorse, and which has been well expressed by deVeer, cited by Marino (1948): "The method of removal should be, if possible, the one that least interferes with histologic examination." It is only when the pathologist has the whole tumour for examination that he is in a position to give a fully valid opinion, and we are therefore opposed to the method of removal sometimes practised, whereby a ligature is tied tightly round the pedicle of a tumour, which is then left to slough away. Though it is certainly true that the detection of an "invasive" tumour is of the greatest importance, we believe that, for the most accurate prognosis, three factors should be taken into account: (1) the extent of spread of the malignant process (i.e., whether it remains "in situ," or is "focal," or has become "invasive"); (2) the grade of malignancy; and (3) the pathologist's assessment as to whether the excision has apparently allowed an adequate free margin of normal tissue round the tumour. There may be occasions when the pathologist will be reluctant to express a definite opinion, but nevertheless we believe that an attempt at assessment along the lines we have suggested will be of great value to the surgeon in deciding the best course for the patient.

MALIGNANT CHANGE IN RECTAL POLYPS

Type of carcinoma	No. of cases	No. of recurrences
Focal	17	Nil
Invasive:		
Low-grade malignancy ..	7	Nil
Average-grade malignancy ..	20	9
High-grade malignancy ..	3	3

From the material presented in this paper we have formed certain opinions about the policy to be pursued when a malignant polyp has been removed. In our series there were 17 "focal" carcinomata, and in none of these patients has recurrence been observed. If the malignant disease is still at the stage of focal carcinoma, local excision is, we believe, sufficient to eradicate the disease. In the case of pedunculated tumours the diathermy snare is probably the most effective method of removal, but for villous tumours the removal of the whole tumour by full-thickness excision, where feasible, is more satisfactory, as advocated by Coffey and Brinig (1950).

It is logical to conclude that, if "focal" carcinomata have done so well after local excision, malignant tumours at an earlier stage of development should have an equally good prognosis. We are accordingly of the opinion that local excision is adequate for cases of carcinoma "in situ." This opinion is at variance with that expressed by Bacon et al. (1951) but in agreement with most other authors.

Where the tumour is definitely "invasive," cure by local excision is less certain, but it is in these cases that we regard histological grading as of value. Of the 4 tumours of high-grade malignancy in our two series, all had lymphatic metastases; so it is obviously unwise to temporise. From our knowledge of the behaviour of rectal cancers of high-grade malignancy and their bad prognosis, it seems that, if any area of high-grade malignancy is reported in a removed polyp, it is wisest to proceed without delay to radical surgery as giving the patient the best chance of survival.

In none of the 7 tumours of low-grade malignancy in our series of local excisions, however, has recurrence been observed; nor were there any lymphatic metastases in the 14 similar cases treated by radical excision. That such tumours can recur is not doubted; but, in view of the low malignancy and lack of tendency to early metastasis, it is safe to assume that evidence of recurrence would become apparent locally before lymphatic spread took place; and, provided that these patients are kept under close observation, the fear of metastasis need not deter the surgeon from pursuing a conservative policy in the first instance. We think it safe to defer radical surgery in these cases, unless there is evidence of recurrence.

The "invasive" tumours of average-grade malignancy are the most common and pose the most difficult problem. In our series 9 out of 20 recurred, and in at least 4 of these lymphatic metastasis was also observed.

In view of these unsatisfactory results from local excision there can be little doubt that the greatest safety for the patient lies in immediate radical surgery: certainly we feel that excision of the rectum should be advised if there is microscopical evidence of spread into the bowel wall, or if the local removal has only left a small and inadequate margin of normal tissue round the malignant tumour. In cases where the malignancy is still confined to the pedunculated tumour, and where the margin of clearance has been good, it is probably safe to defer radical surgery, provided that the patient can be re-examined frequently. Such a policy would, of course, be safer where the lower rectum is involved, because here the earliest sign of recurrence could be detected by palpation, probably before any abnormality became apparent to visual examination. Every case should be most carefully assessed, and the closest collaboration between surgeon and pathologist is needed.

It is appreciated that, when any procedure other than a radical excision is done for a tumour in which malignancy is found, careful and frequent re-examination is essential for the patient's safety. Such frequent re-examination is, however, advisable in any patient from whom a rectal polyp has been removed, even though it may prove histologically to be entirely benign. This has been appreciated for many years (Lockhart-Mummery 1934), and is surely a small price to pay if the rectum can be safely preserved.

Welch (1951) points out the difficulty of detecting recurrence of tumours beyond the reach of the sigmoidoscope, and states that, of 70 polyps in the colon thought to be benign, 11 contained carcinoma. He therefore advised that resection should take the place of colotomy and local excision in dealing with polyps in the colon. The results presented here indicate that recurrence and metastasis are to be expected in many of these polyps after local removal only; nor is it possible to predict without full pathological examination which polyps are likely to recur. In view of the present low mortality associated with uncomplicated colonic resection, it is doubtful if this operation now carries any greater risk than colotomy, and we agree with the views expressed by Welch.

Although it has been shown by the results presented here that certain types of very early focal and low-grade carcinomata have been cured by local excision, this should not be interpreted as advocacy of conservative surgery for established rectal cancer. We still believe that, when a clinical diagnosis of rectal cancer is made, radical excision offers the patient the best chance of survival.

Summary

An attempt is made to give guidance to a surgeon faced with the unexpected discovery of malignancy in a rectal polyp.

A description is given of the early stages in the development of carcinoma, and it is suggested that, when examining a malignant polyp, the pathologist should pay special attention to the extent of local spread of the carcinoma, the histological grade of malignancy, and the presence or absence of a free margin.

The results obtained by local excision in 47 such cases are reported and compared with those obtained by radical excision in 18 similar cases.

It is concluded that local excision of the malignant polyp only is all that is required for most cases at the stage of carcinoma in situ or focal carcinoma, the only exception being anaplastic carcinoma of high-grade malignancy, which always calls for the widest possible removal.

When invasive carcinoma is found in a polyp, the decision as to treatment is much more difficult, and must depend on many factors, of which the two most important seem to be the histological grade of malignancy and the presence or absence of a free margin.

ADDENDUM

Since this paper was written, Fisher and Turnbull (1952) have reported a similar investigation. They have used a classification for malignant polyps based on principles similar to those we have adopted, but differing slightly in details of terminology.

We are grateful to Mr. H. J. R. Bussey, B.SC., of the research department of St. Mark's Hospital, for help in tracing patients and for drawing figs. 1–6. Some of the expenses involved in this work were met by a grant from the British Empire Cancer Campaign, and the follow-up department was assisted by a grant from the Medical Research Council. To both these we offer our thanks.

PRINTERS' ASTHMA

P. B. S. FOWLER
B.M. Oxfd, M.R.C.P.

SENIOR MEDICAL REGISTRAR, BROMLEY GROUP OF HOSPITALS, KENT; FORMERLY ASSISTANT IN THE DEPARTMENT OF RESEARCH IN INDUSTRIAL MEDICINE, LONDON HOSPITAL

THIS paper reviews 32 cases of asthma in printers. These men developed asthma after exposure to a spray, made of gum-acacia and isopropyl alcohol, which is used in colour-printing. This spray is thrown over each sheet and forms a barrier between successive sheets on which the colour-print is still wet. Colour from one sheet is thus prevented from passing on to the back of the next sheet added to the pile. With many spray machines working, the mist can be seen spreading from one printing-machine to the next.

Gums have come into increasing use in industry, and, in the various reports on sensitivity to different gums, acacia, Karaya gum, and tragacanth have been the three most common allergens, in the order listed (Brown and Crepea 1947). Bohner et al. (1941) in America were the first to describe a group of printers with asthma due to sensitivity to gum-acacia. They reported 10 cases and reviewed the literature of isolated reports of sensitivity to inhaled acacia. In Canada Sprague (1942) reported a further case of asthma in a printer sensitive to inhaled acacia. The disease has not been described in printers in this country.

Bohner et al. (1941) showed conclusively by passive transfer tests that the printers who developed asthma were sensitive to the gum-acacia in the spray fluid.

MATERIAL

The first patient attended a general medical outpatients department complaining of asthma which he believed was due to the spray fluid to which he was exposed at work. A few weeks later 31 further printers were examined. They came in response to a letter sent to London printing chapels asking members who thought they were affected by the spray fluid to attend for examination.

TABLE I—EFFECT OF INHALED GUM-ACACIA ON 63 PRINTERS

Reaction to inhaled acacia	No. of printers complaining of symptoms	No. of printers employed by one firm and routinely examined	Total
No symptoms attributable to spray fluid	4	13	17
Early symptoms of sensitisation to gum-acacia	2	12	14
Asthma resulting from exposure to gum-acacia ..	26	6	32
Total	32	31	63

Finally another 31 printers, comprising the staff of a firm engaged largely on colour-printing, were examined. In this firm 2 men were on holiday and not seen.

The effect of inhaled acacia on these 63 printers is shown in table I.

After the clinical picture of the 32 florid cases of asthma had been established, it became clear that 14 other printers had typical early symptoms of asthma although the full clinical picture had not developed.

PAST HISTORY AND FAMILY HISTORY OF ALLERGY

In 26 of the 32 printers with asthma there was no past history or family history of allergy preceding exposure to the spray fluid.

One man gave a previous history of bronchial asthma. He had suffered from infancy with eczema and bronchial asthma. He had lost no schooling from his attacks, which were mild and ceased at the age of 14. Now aged 22, he had been a printer for five years and exposed during this period to the spray fluid. For the last two years he had had attacks of asthma an hour after exposure.

A second man had a sister with bronchial asthma, and had himself had hay-fever since childhood.

A third man had a son, aged 5 years, who had had eczema of the face at the age of 1 year, followed by flexural eczema and asthma.

Two other men had had attacks of hay-fever every spring since childhood.

The grandfather of a sixth man had asthma.

DURATION OF EXPOSURE BEFORE SENSITISATION

The average duration of exposure before asthma *developed in these 32 printers was 4·8 years.*

In 4 cases exposure to spray fluid had lasted for ten years or more before symptoms developed (see table II).

TABLE II—DURATION OF EXPOSURE BEFORE SENSITISATION IN 32 PRINTERS WITH ASTHMA

Duration of exposure	Less than 1 yr.	1–2 yr.	3–4 yr.	5–10 yr.	More than 10 yr.
No. of cases ..	2	11	8	7	4

In 2 the exposures had for long periods been slight. In the other 2 there had been heavy and prolonged exposure. The period of exposure before symptoms developed could not be related to the amount of spray to which they were exposed. The concentration of spray fluid could only be estimated roughly. Most of the men had been exposed to increasingly heavy concentrations through the last few years because additional spray machines had been added to the printing-presses.

In the 6 printers with a past or family history of allergy the average duration of exposure before symptoms developed was 2·4 years. In the remaining 26 the corresponding figure was 5·3 years.

CLINICAL PICTURE

The onset was gradual in 28 cases and abrupt in 4.

The printer first notices that the nose becomes blocked and the throat feels constricted at the end of a day when there has been a heavy concentration of spray. Sneezing and an irritating cough are common early symptoms. "Colds," which have previously lasted a few days, continue for weeks.

The earliest evidence of asthma is a wheezing in the *chest noticed by the printer, at first only when he has a* "cold." Later he may experience wheezing on first rising in the morning but is free from symptoms on Sunday and Monday. Over a few weeks or months attacks of bronchial asthma increase in severity, and the man becomes incapacitated after exposure to the spray fluid.

ILLUSTRATIVE CASES

Case 1.—A man, aged 37, had been a printer for twenty-three years and exposed to spray fluid for six years. For the first five years' exposure to spray fluid he remained well. He then noticed the gradual onset at work of symptoms referable to the upper respiratory tract. He sneezed frequently at the end of the day. His nose became blocked and his throat felt tight. An irritating cough troubled him. Over a period of six months these symptoms increased and he began to have attacks of asthma three or four hours after being exposed to spray fluid. The attacks persisted all evening, but he was free *from symptoms on waking next morning.*

There was no past history of serious illness, and before his present symptoms he had never had asthma, hay-fever, or urticaria. There was no history of allergy among his parents and eight siblings.

He looked fit and was an intelligent and reliable witness. Loud expiratory rhonchi, typical of bronchial asthma, were heard over both lung fields. The remainder of the physical examination was negative.

TABLE III—DURATION OF IMMEDIATE EXPOSURE BEFORE ASTHMA DEVELOPS

Time	Less than 1 hr.	1–3 hr.	4–7 hr.	8 hr. or more	Variable (see text)
No. of cases	3	12	9	5	3

Radiography of the chest showed clear lung fields. A skin sensitivity test with the spray fluid gave a strongly positive reaction.

The patient was forced to change his job to avoid the spray fluid, and immediately lost all his symptoms. When examined a week after exposure to spray fluid had ceased, no adventitious sounds were heard in the lungs.

Although the onset is usually gradual, in 4 cases the *onset of asthma was abrupt. The following* is an example.

Case 2.—A man was exposed to spray fluid for three years. The first year he noticed no symptoms on exposure to the spray. One Friday evening he started to cough and became breathless. Bronchitis was diagnosed, and he remained off work for three weeks. On the day he returned to work he felt *well until the afternoon,* when he suddenly developed an attack of asthma. He has since invariably had asthma five or six hours after any heavy exposure. The attacks subside two hours after leaving the spray fluid.

Asthma usually develops some hours after exposure to the spray fluid (see table III).

Three printers gave histories which suggested that the length of exposure each day before the onset of symptoms depended on the exposure during the days immediately before.

Case 3.—A man noticed symptoms at 3·30 P.M. on Monday after a weekend away from work. The attacks would develop *an hour earlier on Tuesday. By Thursday* the symptoms often started at 10 A.M. and persisted to the next day. This printer has avoided spray fluid for two years and remained free from symptoms.

Case 4.—A man developed asthma starting each week at 4.30 P.M. on Monday. *By Friday* the attacks would begin at noon. Since avoiding the spray he has remained well.

Case 5.—A man, working at night, found that with a five-night week the attacks of asthma would come on earlier and more severely as the week progressed. By working a four-night week with a break in mid-week he is little troubled by his attacks of asthma.

TABLE IV—TIME TAKEN FOR SYMPTOMS TO SUBSIDE AFTER CESSATION OF EXPOSURE

Time	Less than 1 hr.	1–2 hr.	3–5 hr.	6 hr. or more	Indefinite
Persons	6	6	4	11	5

All 32 printers thought that the severity of the asthma varied with the amount of spray fluid they inhaled.

The time taken for symptoms to subside after the men ceased to be exposed to spray fluid varied considerably (see table IV).

DISCUSSION

In the London printing industry about 500 printers are exposed to the spray fluid. The work is highly skilled, and printers are loth to change to the less remunerative black-and-white printing. For this reason it was unlikely that all printers affected by spray fluid would be willing to submit to examination.

One printer, among those routinely examined from the one firm, at first maintained that he had no symptoms attributable to the spray. He was actually distressed at the time of examination and had severe bronchospasm. He later gave a history that left no doubt that his asthma resulted from exposure to spray fluid.

It was known that many printers with asthma had not responded to the letters to their chapels asking them to attend for examination. For example, none of the 6 printers with asthma found in the one firm had come in response to the original letters sent to their chapels. Many printers with asthma knew colleagues who had left colour-printing because of symptoms similar to their own.

For these reasons the incidence of asthma in the one printing firm gives a better indication of the extent of the industrial hazard. The firm chosen for the investigation used the spray fluid extensively. The management had installed exhaust ventilation and fitted an automatic device to stop the ejectors from spraying fluid when the printing-machine stopped. This useful device had not been fitted at other colour-printing works visited.

Of 31 workers in this firm, 19% had printers' asthma. Probably the incidence would be as high in other firms doing colour-printing.

The number who had already left the firm to avoid the spray fluid was not known. One printer, who came for examination in response to a letter to his chapel, had developed asthma in this firm but had left before the investigation there was made.

An ominous indication of this hazard to printers is the high proportion of men who had early symptoms of asthma. Of the 12 men in one printing firm who had early symptoms, 8 complained of some wheezing and a feeling of tightness in the chest. Although not yet incapacitating, these early symptoms were by no means trivial.

The efficiency of the industry has not yet been affected, because many printers take a long time to become sensitised and the spray fluid has only been used in heavy concentrations since the late war. The disease, however, has already caused much suffering to individual printers.

Although it is well recognised that, once a person develops asthma, multiple sensitivity tends to develop, this has not yet happened in any of these 32 cases; they all remain well when not exposed to spray fluid.

Efficient ventilation can only mitigate the hazard. It can be eradicated by the substitution of dextrose for gum-acacia, as Bohner et al. (1941) suggested.

SUMMARY

Asthma is reported in 32 printers exposed to a spray fluid containing gum-acacia. A further 14 printers had symptoms of sensitisation to the spray fluid.

The average duration of exposure before asthma developed was 4·8 years, but the period of exposure was half as long for the 6 printers who had a past or family history of allergy.

In one firm 19% of the printers had asthma and a further 30% had early symptoms of asthma due to sensitisation to the spray.

This industrial hazard can be eradicated by the substitution of dextrose for gum-acacia in the spray fluid.

I am grateful to Dr. N. S. Plummer for the encouragement and help he has given me in preparing this paper. I am also indebted to Mr. P. Astins, C.B.E., secretary, and Mr. F. R. Norman, assistant and organising secretary, of the Printing Machine Managers' Trade Society, who gave me every facility to make this investigation on members of the society.

EFFECT OF INTERRUPTED COURSES OF CHLORAMPHENICOL ON RELAPSE-RATE IN TYPHOID FEVER

A. T. JOHN
M.D., B.Sc.
TUTOR IN MEDICINE, STANLEY MEDICAL COLLEGE, MADRAS; ASSISTANT PHYSICIAN, GOVERNMENT STANLEY HOSPITAL

V. S. VINAYAGAM
M.B.
HON. ASSISTANT PHYSICIAN, GOVERNMENT STANLEY HOSPITAL

THE effect of chloramphenicol on the course of typhoid fever is uniformly good, but the rate of relapse is high (see table I).

In attempts to prevent relapses, administration of the drug has been prolonged for some days after fever and other symptoms have subsided. The lowest relapse-rate so obtained was 16% in the 25 cases reported by Woodward et al. (1948). Therefore a search for a more efficient method of preventing relapses was indicated; and administration of chloramphenicol in interrupted courses (Smadel 1950) seemed to us to be the one most likely to succeed.

TABLE I—RELAPSE-RATES IN TYPHOID FEVER TREATED WITH CHLORAMPHENICOL

Reference	No. of cases	No. of relapses
Smadel et al. (1948)	10	2 (*20%*)
Hill et al. (1950)	25	12 (*57%*)
Woodward et al. (1948)	25	4 (*16%*)
Chatterjee (1950)	24	4 (*17%*)
Lantin et al. (1951)	23	7 (*30%*)
Cook and Marmion (1949) ..	14	3 (*21%*)
Total	121	32 (*26%*)

We report here the response of 20 cases of typhoid fever to interrupted courses of chloramphenicol, compared with those of 17 cases to single continuous courses.

We observed that, in almost all our cases of typhoid fever treated with single continuous courses of chloramphenicol, relapses occurred, if at all, between the ninth and the twenty-second days after the patient had become apyrexial (table II). Therefore, to prevent relapses, instead of continuing the administration of chloramphenicol uninterruptedly for so many days after clinical cure, we withdrew it soon after the pyrexia had subsided, and started a second course just before the earliest time at which a relapse might be expected.

METHOD

As soon as typhoid fever was diagnosed, the patient was given chloramphenicol 0·25 g. two-hourly till his

* Calculated from the day the patient became apyrexial. Relapses were confirmed by positive culture.

Case 1.—Patient developed a parotid abscess from which streptococci and staphylococci were isolated.

Case 15.—A second course was started but not completed, because no more chloramphenicol was available.

temperature touched normal. Thereafter chloramphenicol 0·25 g. was given four-hourly till the patient had been apyrexial for forty-eight hours. No chloramphenicol was given in the next five days. On the sixth day (the eighth day after pyrexia had subsided) a further course was started, consisting of chloramphenicol 0·25 g. six-hourly *for six days. All the cases treated in this way* are included in table III. We should mention, however, that, because of the high cost of the drug, it was not possible to give chloramphenicol to all patients with typhoid fever admitted during the investigation. Only two categories of patients received it: (1) all those who could afford to pay for it; and (2) those who could not afford to do so, in whom pyrexia, toxæmia, and other symptoms were severe.

Table II gives details of 17 cases of typhoid fever treated with single continuous courses of chloramphenicol. Most of them received chloramphenicol for some days after pyrexia and other symptoms had subsided. Of these 17 cases, 10 were treated before the new dosage scheme was introduced. The remaining 7 are from the early stages of the investigation when alternate cases were given continuous as opposed to interrupted courses of chloramphenicol. During the later stages of the investigation all the cases were given interrupted courses, because this method had proved superior to continuous courses in preventing relapses. Further, the administration of chloramphenicol in interrupted courses proved more economical of the drug, which was costly and scarce.

All the patients received general treatment along accepted lines—i.e., rest in bed, a restricted high-calorie low-residue diet, careful nursing, and vitamin supplements. (Vitamin supplements are very important in cases derived from a population constantly on the brink of nutritional deficiency.) These measures were all continued for twenty days after pyrexia had subsided. This was considered necessary in view of the fact that, in cases treated with chloramphenicol, complications—e.g., perforation and hæmorrhage—have developed even after pyrexia and other symptoms had subsided, thereby indicating that the pathological processes in the intestines take time to heal (as long as the usual clinical course in cases not given chloramphenicol), though clinical cure has apparently taken place.

RESULTS

Three patients with typhoid fever died during treatment with chloramphenicol. All of them had severe toxæmia, and death took place early in the course of the treatment. They are excluded from the tables.

Of 20 cases of typhoid fever treated with interrupted courses of chloramphenicol 1 relapsed, the relapse-rate thus being 5%. Of 17 cases of typhoid fever treated with single continuous courses of chloramphenicol 7 (41%) relapsed. Of these 17 cases 12 had *chloramphenicol* for six days or more after they had become apyrexial; and 4 (33%) of these relapsed. The two groups of cases in tables II and III are comparable as regards age, sex, general immunity, and nutritional status. The source of infection in all the cases in both the groups was the city of Madras, where typhoid fever is endemic. As already stated, the lowest relapse-rate hitherto published is 16%.

In the present series the average quantity of chloramphenicol given to each of the 20 patients treated with interrupted courses was about 19 g. (table III), whereas the average quantity given to each of the 17 patients treated with single continuous courses (including the quantity used for treating relapses) was about 22 g. (table II).

CONCLUSIONS

Interrupted courses of chloramphenicol seem to give better results than do continuous courses in preventing relapses in typhoid fever. The relapse-rate is highest when chloramphenicol is withdrawn soon after the pyrexia has subsided; it is lower when chloramphenicol therapy is continued for some days after clinical cure; but it is lowest when chloramphenicol is given in interrupted courses, being withdrawn soon after clinical cure and given again just before a relapse can be expected.

The average quantity of chloramphenicol used in interrupted courses is less than that used in continuous courses—an important consideration in the case of so expensive a drug.

We wish to thank Dr. K. C. Paul, on whose suggestion and under whose guidance this work was done; Dr. C.

18	M 10	6	4	12	6	18	+ +	+ + +	Nil
19	M 7	6	4	12	6	18	+ + + +	+ + + +	Nil
20	F 21	9	3	11	6	17	+ + +	+ + + +	Nil

* In some cases the history of duration of fever was vague, conflicting, or otherwise unreliable.

Case 11.—This case was diagnosed and partly treated before admission to hospital.

Case 13.—Developed parotitis, with pyrexia, on 8th day of normal temperature, but cultures of blood, urine, and fæces were negative.

Case 15.—Second course curtailed owing to lack of drug.

Case 16.—The period of 24 days before the start of the relapse is longer than in any case given a single course. This delay is probably due to the second course. The relapse was very mild.

Raghavachari for supplying chloramphenicol for many of the cases and for permission to publish; Dr. P. K. K. Raja for allowing us to include some of his cases; and the house-staff and nurses for their willing coöperation.

THE TRENDELENBURG POSITION

JOHN HOWKINS

M.D., M.S. Lond., F.R.C.S., F.R.C.O.G.

ASSISTANT OBSTETRICIAN AND GYNÆCOLOGICAL SURGEON, ST. BARTHOLOMEW'S HOSPITAL, LONDON

THE surgeon who operates in the pelvis, whether it be on the bowel or on the urinary or genital tract, needs a clear field. To obtain this he will use some degree of Trendelenburg's tilt. With a well-trained team this presents little difficulty, but there are certain problems inherent in the position which may be a source of danger to the patient and embarrassment to the surgeon:

(1) The safe suspension of the patient in the tilted position.
(2) The disposal of the arms so that, while they are available for intravenous injection and infusion and the recording of the blood-pressure, they do not hinder the surgeon.
(3) The care of the legs.
(4) Some method of providing a small instrument table so that the surgeon's tools do not slip down the patient into the wound or on to the floor.

SUSPENSION OF PATIENT

There are three methods of suspending the patient.

(1) *Support by Shoulder Rests.*—The whole weight of the patient is taken on the shoulders; and if, in addition, the arm is abducted for intravenous and other manipulations, there is a real risk of brachial palsy. Several cases have been recorded and many more have occurred which have not been recorded.

Another criticism is that the thorax is compressed by the weight of the abdominal viscera above and the shoulder supports below, leading to a decrease in the vital capacity. Any surgeon who doubts this statement should have a flight in an old-fashioned aircraft, like an open Moth or Magister, in the inverted position, after being carefully strapped in: he will then appreciate the weight of his own viscera on the diaphragm and the difficulty in respiration which the unconscious patient must suffer.

(2) *Suspension by the Legs.*—This is effected by bending the table at the knee-joints so that the knees are flexed to almost a right angle. This is efficient but open to the criticism that it injures the veins of the gastrocnemius and soleus muscles and impedes the venous return from the leg by kinking the popliteal veins. I suggest that those surgeons who use this method of suspension should try it on themselves, with the table tilted: they will then appreciate the very great weight put upon the legs. It is theoretically possible that the common incidence of phlebothrombosis after pelvic operations is partly caused by the trauma to the calf veins inherent in this method of suspension, which may also cause palsies from too tight and improperly padded strapping of the legs.

(3) *Ogier Ward's Iliac-crest Supports.*—These supports, which have now been made for me by Allen & Hanburys in two sizes—one for fat and one for thin patients—fix the patient firmly and efficiently somewhere near her centre of gravity, leave the thorax and legs unembarrassed, and have been used by me for nearly five years in four hospitals. Their proper adjustment needs special drill on the part of the operating-theatre personnel: it takes a little longer than other methods but is absolutely efficient. Since using these supports I have had no fatal cases of pulmonary embolism after abdominal operation.

A modified form of the supports was described by Mr. Stanley Hans in THE LANCET of Oct. 4, 1952, p. 664.

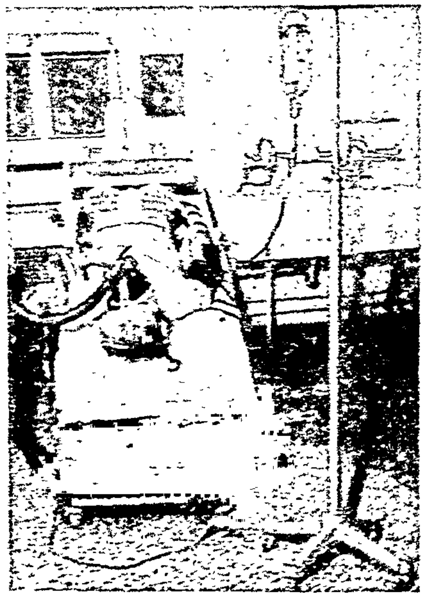

Fig. 1—Trendelenburg position, showing the two positions of the arms, leaded arm rests, pelvic-crest supports, operating-table, and extended legs.

DISPOSAL OF ARMS

The arms may be folded on the chest, and the dorsum of the hand secured with strapping to the chest wall (fig. 1); in this position intravenous injections and infusions can be given by the anæsthetist using the veins on the back of the wrist and hand. An alternative method is to place the arm alongside the patient (fig. 1) and to secure it there with lead arm-rests which can be bent to suit any size and shape of limb. It is important to pad all metallic protuberances which could injure the arm. The use of a wooden abduction splint, either on one or both sides of the patient, is dangerous because gravity and the movements of assistants during the operation tend to abduct the arm more and more, thereby causing brachial palsy—a serious and actionable disaster. Special attention should be paid, by a responsible person, to the firm fixation of the arms, because nothing is more annoying than having to stop an operation to secure an arm which has slipped out of position. Fig. 1 also shows how intravenous and blood-pressure apparatus may be applied.

CARE OF THE LEGS

The legs should be quite free and unencumbered by any retaining straps. They should also be straight, since angulation at the knee can only interfere with venous return and lead to stagnation, increasing the danger of phlebothrombosis. The calves should be well padded, because the average operating-table 'Sorbo' mattress is far too thin. Some surgeons use small sorbo rings on the balls of the heels to take some pressure off the calf muscles. The most important thing, however, is a really thick mattress.

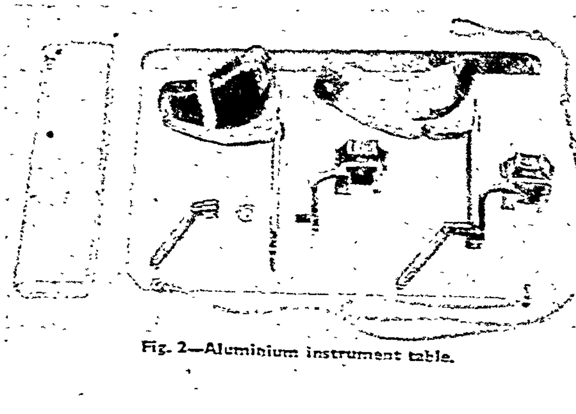

Fig. 2—Aluminium instrument table.

INSTRUMENTS

After experimenting with tables independent of and attached to the operating-table, I have come to the conclusion that the best, cheapest, and most efficient method of providing an instrument table for the surgeon is to take a piece of aluminium 18 in. wide by 12 in. long, bend up one end for $1^{1}/_{2}$ in., drill a hole $1^{1}/_{2}$ in. from the side and $^{1}/_{2}$ in. from the top at each end, and tie a piece of string through the holes. The surgeon then has an instrument stand which he can put as high or as low on the patient as he pleases and cut to a size acceptable to his own fancy (fig. 2).

SUMMARY

The Trendelenburg position, when properly employed, should be safe for the patient and comfortable for the surgeon and his assistants.

Three methods of suspending the patient are described, of which suspension by Ogier Ward's iliac-crest supports is considered the best.

The disposal of the arms and legs is described, and special emphasis is placed on the risks of brachial palsy when shoulder rests are used with the arms abducted. Suspension of the patient with the knees flexed may well favour phlebothrombosis in the veins of the calves.

A simple, cheap, and efficient instrument tray is described.

I should like to thank the photographic department at St. Bartholomew's Hospital for assistance with the illustrations.

Medical Societies

ASSOCIATION OF CLINICAL PATHOLOGISTS

THIS association met in London on Oct. 2–4. During the course of the meeting Prof. R. J. V. PULVERTAFT delivered a presidential address, on the Individual and the Group in Modern Medicine; and Dr. S. C. DYKE gave the first Foundation lecture, on the Development of the Concept of Pernicious Anæmia.[1]

Benign Polypoid Gastric Tumours

Dr. H. G. H. RICHARDS (Winchester) classified benign tumours of the stomach as adenomas, pancreatic rests, fibromas, leiomyomas, neurogenic tumours, lipomas, angiomas, and miscellaneous rarities. At his own hospital such tumours formed about 10% of all gastric tumours (6 benign and 53 malignant). Epithelial polyps varied from what amounted to simple hypertrophy of the gastric mucosa to frankly adenomatous tumours with early malignant change. Dr. Richards described a case of polypoid gastric tumour due to a pancreatic rest, and commented on the absence of islet tissue. He also described three cases of leiomyoma, pointing out the importance to the radiologist of the central crater in these tumours.

Pathology of Gastric Arteries

Dr. G. R. OSBORN (Derby) said that although it had been taught for over a hundred years that peptic ulcer was related to arteriosclerosis the gastric arteries were practically free from the usual forms of sclerosis. In 1951 there were 327 partial gastrectomies at the Derbyshire Royal Infirmary; arteriosclerosis was not seen in any of these. The gastric vessels were examined in 32 sudden deaths from coronary thrombosis. There were 25 males aged 41–85 (average 61) and 7 females aged 55–82 (average 74). The gastric vessels were all normal with 4 minor exceptions: 3 had localised lesions of inflammatory origin; only 1 (a woman of 74) had an atheromatous plaque, and this was too small to affect lumen size. The splenic and superior mesenteric arteries did not share this immunity from sclerosis. Possibly the five series of anastomoses protected the gastric arteries from stresses which produced sclerosis elsewhere. Arterial lesions related to peptic ulcers should be termed chronic, subacute, or acute erosion. In chronic erosion mucinous infiltration of the intima greatly reduced lumen size; this was the main reason why every peptic ulcer did not cause fatal bleeding. In subacute erosion there was an organising thrombus at the distal (eroded) end; elsewhere the artery was normal. The typical lesion of fatal hæmorrhage was acute erosion; this would lead to death if gastrectomy was not performed in the pre-uræmic stage.

Difficulties with Antibiotics

Dr. J. D. A. GRAY said that antibiotics had conferred such benefits on mankind that their dangers had tended to be overlooked. The toxic effects, such as damage to the 8th nerve by streptomycin and the blood dyscrasias after chloramphenicol, were now well known and could usually be avoided. Modern penicillin was non-toxic but large doses intrathecally were dangerous. Sensitisation of patients to antibiotics had occasionally produced alarming effects. To prevent sensitisation penicillin should not be used for minor skin ailments. Sensitivity to one antibiotic might imply sensitivity to others. It was difficult to determine whether the mucous membrane lesions were due to avitaminosis or to a change in the flora. When penicillin was used as a prophylactic in surgery of the urinary tract or meninges, infections with *Pseudomonas pyocyanea* were common and might be prevented by giving a sulphonamide at the same time. After antibiotic therapy moniliasis might occur in the alimentary, respiratory, and urinary systems, and might be fatal in a lung abscess or bronchiectatic cavity. When an organism became resistant during treatment, further administration of the antibiotic might harm the patient and expose his contacts to infection with resistant organisms. The incidence of resistance was increasing. Antagonism between bactericidal and bacteriostatic antibiotics fortunately seemed to be limited to cases where the organism was sensitive to the bactericidal drug.

Origin of Visceral Melanomata

Dr. O. C. LLOYD (Bristol) described a case of primary melanoma of the adrenal gland with multiple metastases. Sixteen other instances had been described; in four of these there were no metastases, so there could be no doubt that primary melanomata did occur in the adrenal. Specific silver stains for melanin showed granules to be present in 57% of 44 human adrenals examined, irrespective of age or sex. They were found in the cytoplasm of the adrenal medullary cells (phæochromocytes). The cells affected were often scanty. Fontana's silver solution applied for eight hours or less was not quite specific for melanin, as claimed by Masson, since it also blackened the pigment of ganglion cells. Baker's[2] method was to use 5% silver nitrate at 37°C for one to two hours. Used for only one hour, it would blacken nearly all true melanin, including that found in the phæochromocytes. All adrenal pigments, including melanin, were bleached by nascent chlorine. Dr. Lloyd concluded that adrenal melanomata were derived from medullary phæochromocytes, and that the fact that they could be melanogenic was scarcely surprising in view of their common origin from the neural crest with the melanoblasts of the skin and meninges.

Lingula Biopsy in Mitral Stenosis

Dr. J. B. ENTICKNAP said that specimens had been taken from the lingula segment of the upper lobe of the left lung during operations for mitral stenosis, in the hope that examination of them would be useful in assessing prognosis. They had not been found of much value in individual cases, but some useful information has been derived from the series as a whole. While the parenchymal changes in the lingula were not typical of the entire lung, the vascular changes did appear to be so. Arteriolar sclerosis and hypertrophy were common, and both reduced the vascular lumina; as these occurred in similar morbid physiological conditions they had been assessed together by measurement of lumen/wall ratios. Considerable reduction of the lumina was seen, the mean ratio being about 4 : 1. All the patients had pulmonary hypertension and the lower ratios occurred with the higher pressures. A significant correlation was discovered which could be expressed by the formula:

$$\text{Arteriolar lumen/wall ratio} = 21{\cdot}3 - \frac{\text{mean pulmonary artery pressure}}{3{\cdot}03}.$$

Arteriolar hyalinisation was not seen in these sections; a possible explanation of this was to be found in the fact that he highest pulmonary systolic pressure in these patients 120 mm. Hg) was much less than that found in the brachial rtery in cases showing renal arteriolar hyalinisation. In two ases with necrotising arteriolitis the pressures were about 20 mm. lower than the highest in this series, and both showed ither histological or clinical signs of active rheumatism. It seemed probable therefore that arteriolar necrosis in mitral stenosis was related to circumstances other than simple excessive strain. Capillary dilation was seen in about a third of the cases; in these the pressures did not differ from those of the remainder, and they showed no arteriolar changes.

Differentiation of Primitive Leukæmic Cells

Dr. D. ROBERTSON SMITH (Cambridge) described a method of differentiating myeloblasts, lymphoblasts, and monoblasts by a simple in-vitro culture method. The bone-marrow or peripheral blood is placed in heparinised Tyrode solution, and the nucleated cells are separated by centrifugation or sedimentation. Cultures are set up in a medium consisting of equal parts of serum from the patient and Tyrode solution, the final cell concentration being about 2000 per c.mm., and 3 ml. amounts are placed in each of three McCartney bottles. A total and differential count is made, and bacteria (either staphylococcus or *Bacterium coli*) are added to one tube. The bottles are incubated at 37°C and examined after 4 hours and 24 hours. Dr. Robertson Smith said that myeloblasts showed evidence of maturation into promyelocytes and myelocytes after 24 hours, but showed no phagocytic activity. Lymphoblasts did not mature or show phagocytic activity in vitro, but degenerated rapidly into smear-cells. Monoblasts were highly phagocytic in culture and developed into more mature forms. In the Naegeli type of monocytic leukæmia some of the blast cells were phagocytic (monoblasts) and others non-phagocytic (myeloblasts), whereas in the Schilling type all were phagocytic. This simple in-vitro culture method was valuable where routine methods of distinguishing primitive leukæmic cells failed.

Antihæmophilic Potency of Plasma

Dr. W. R. PITNEY (Melbourne) and Dr. J. V. DACIE described a method of studying the generation of thrombin in recalcified citrated plasma by means of subsampling into fibrinogen solution. Normal thrombin generation curves were contrasted with the far slower evolution of thrombin in hæmophilia.

Cytochemical Methods in Hæmatology

Dr. F. G. J. HAYHOE (Cambridge) discussed cytochemical staining methods used in hæmatological research from the viewpoint of their applicability to routine diagnostic work. The *Feulgen reaction* specifically demonstrated desoxyribonucleic acid which was confined to the cell nucleus. The pattern of nuclear staining resembled that seen in a good Leishman preparation. The intensity of the reaction increased with maturity of the cell. Nucleoli were invariably negative and surrounded by a strongly positive ring of nucleolus-associated chromatin which made them readily recognisable. The reaction had practical value in routine hæmatology in assessing cell maturity, enumerating nucleoli, and defining nuclear chromatin patterns. The demonstration of glycogen by the *periodic acid-Schiff reaction* gave consistent results, and the method was satisfactory and valuable in academic studies. Glycogen was confined to the cell cytoplasm. The erythropoietic series was negative at all stages. The myeloid series showed increasing numbers of positive granules with increasing maturity; eosinophil granules were negative against a positive cytoplasmic background. Lymphocytes and monocytes contained small amounts of glycogen. No significant variations in cell-glycogen content seemed to occur in blood dyscrasias, however, and the method had no great practical application in diagnostic work. *Sudan black B* stained lipids excellently. The myeloid series showed increasing numbers of positive granules with increasing cell maturity. Eosinophil granules showed a positive periphery with unstained centre. Basophil granules were negative. Lymphocytes were negative; but monocytes contained scattered granules. Although cells from blood disorders did not greatly differ in reaction from comparable normal cells, the reaction was of diagnostic value in demonstrating positive granules in early cells of the myeloid and monocytic series. For this purpose Sudan black seemed superior to the commonly used peroxidase reaction. The *techniques of Gomori* for demonstrating acid and alkaline phosphatase were too unreliable for routine work.

Coagulation Defect in Tromexan Therapy

Dr. A. S. DOUGLAS (Oxford) described an investigation designed to elucidate the prolonged one-stage clotting-time following the administration of 'Tromexan.' Factor v was found to be normal. The addition to tromexan plasma of small proportions of normal serum, which contained no prothrombin, was found to shorten the one-stage clotting-time often to normal, while tromexan serum was deficient in this property. This action of serum was its factor VII property. Therefore the one-stage test in tromexan therapy reflected a deficiency other than that of prothrombin. From study of the plasma in a case of idiopathic prothrombin deficiency (a very rare condition) a new two-stage method for measuring prothrombin had been devised. This patient's plasma, with 10% prothrombin by this method, had a one-stage clotting-time only slightly prolonged, and his plasma corrected the defect in tromexan plasma as well as did normal plasma. By the two-stage technique the prothrombin content of tromexan plasma was only occasionally found to be lower than 40% of normal, and usually it lay between 40% and 100%. In tromexan therapy the one-stage clotting-time measured factor VII rather than prothrombin. By these methods the effect of therapy on prothrombin and factor VII was followed. The factor VII dropped at the start of therapy to a very low level, the prothrombin some days later and to a much smaller extent.

Iron in Sternal Marrow Biopsies

Dr. H. E. HUTCHISON (Glasgow) had estimated the amount of stainable iron in sternal aspirates by the prussian-blue reaction. In disorders of the blood this procedure provided a simple means for the control of iron therapy. In an anæmic subject the absence of stainable iron meant that the patient was iron-deficient, and in Dr. Hutchison's opinion this technical method gave the most decisive hæmatological indication yet devised of iron deficiency and of the necessity for iron therapy. The converse had also proved true—if stainable iron was present in the marrow the anæmia would not be improved by the administration of iron whether by mouth or intravenously. Over the past two years, used in this way for the control of iron therapy, the method had not failed, and it had proved possible to predict when an anæmia would be likely to respond to iron. The method also indicated when enough iron had been given and so could obviate the danger of overdosage when iron was being administered intravenously. The method might possibly help to distinguish the hypochromic anæmias of chronic intoxication from those due to iron deficiency.

Tubeless Test-meal

Dr. JOHN HARKNESS and Dr. J. A. DURANT (Portsmouth) reported their results with Segal's tubeless gastric analysis. This depended on the power of the hydrogen ion of free hydrochloric acid in the gastric juice at a pH below 3 to displace the quininium ion of a quininium-resin compound; the liberated quinine was absorbed from the intestine and excreted in the urine where it could be estimated readily. Segal's quininium-resin indicator was not available commercially in Britain, but an equivalent product had been made from material available here. 124 duplicate gastric analyses were made in 104 subjects by the ordinary alcohol method and the quinine-resin method. Histamine had to be given in some cases to ensure the secretion of hydrochloric acid for both methods. The patients with free hydrochloric acid excreted considerably more quinine than did the achlorhydrics—the results of the two groups did not overlap. Four patients had discrepancies; two patients with free HCl could not excrete quinine because of poor renal function, one achlorhydric patient excreted quinine because of interference by aluminium silicate therapy, and one apparent discrepancy was still being investigated to decide which method was actually yielding the correct results. The achlorhydrics with pernicious anæmia excreted less quinine than achlorhydrics following partial gastrectomy. Wider trials of the new technique were recommended.

Values for Blood Constituents

Dr. I. D. P. WOOTTON and Prof. E. J. KING said that normal values for most of the commonly determined blood constituents had now been determined. Only some of the constituents were distributed among the population as "normal curves"; almost all the remainder showed frequency distributions which were skew and fitted by lognormal curves. Tables had been calculated showing the limits within which 80% and 98% of the population of healthy people fell. To determine the possibility of using these tables in other hospitals, agreement between hospitals had been examined. One blood sample and one synthetic solution had been analysed and reported by 25 and 36 laboratories respectively. For most constituents there were very wide variations in the results, the highest figures reported being 2–5 times the lowest figures, although results for the solution were better than for the blood. This gave a very bad impression of the reliability of the work of clinical laboratories. In the case of hæmoglobin measurements an attempt had been made to improve the situation by the Medical Research Council hæmoblogin standard scheme, operated from the Postgraduate Medical School of London.

Action of Calciferol in Lupus Vulgaris

Dr. G. WETHERLEY-MEIN described the results of a study in which standard virulent tubercle bacilli (H37RV) were cultured and subcultured on a variety of media containing calciferol in concentrations of 50–100,000 units per ml. of medium. Certain strains were subcultured at intervals of about thirty days for over two years. Calciferol had no effect on the rate of growth, the colonial or bacillary morphology, or the virulence. Similar studies using lupus strains of attenuated virulence showed that these also were unaffected by culture and subculture in the presence of calciferol. The sera of various tuberculous and non-tuberculous patients receiving high doses of calciferol (150,000 units daily) had no effect on the growth or morphology of tubercle bacilli. The rate of healing and histological changes occurring in experimental wounds in guineapigs were in no way modified in animals receiving high doses of calciferol. These findings coupled with other observations[3] suggested that calciferol itself acted by enhancing the specific cellular reaction of the body to the chemical fractions of the tubercle bacillus following local accumulation of the vitamin in the skin.

Detection of Potassium Deficiency

Dr. L. NAFTALIN (Lincoln) said that in the postoperative state the amount of potassium excreted in the urine was correlated with the clinical condition. The relation was not a directly causative one in every case, but it had been found that patients with good nutritional status excreted a larger amount of potassium and had an easier clinical course than the more poorly nourished patients who were unable to excrete potassium. At present this was usually recognised only after the event; and Dr. Naftalin proposed an approach to the earlier detection of potassium deficiency based on the finding of a high serum-bicarbonate, low serum-chloride, normal or near normal serum-sodium, and reduced food intake.

Paper-strip Electrophoresis

Prof. N. H. MARTIN said that analysis of serum-proteins by paper-strip electrophoresis had become a routine technique in many laboratories. In his own laboratories, exercised by the atypical separations that he believed one was liable to get when the serum-proteins were dried on the filter-paper, he had been elaborating "wet boundary" techniques; this involved some loss of clarity of outline. A rigid comparison with the classical electrophoresis showed that differentiations achieved by the old technique were not constantly mirrored in the new. The variation in mobilities obtained with purified fractions, whether using dextran or albumin markers, indicated that these could only form the crudest means of identification. Quantitative studies showed that the binding capacities of the various proteins differed so much that correlation between the classical and the paper method by dye-elution techniques was impossible without some form of correction factor. It was impossible, with present knowledge, to forecast how far empirical correction factors for normal sera were valid for pathological sera. It was difficult to understand the good agreement obtained by some workers between the classical and the paper technique using the Folin reagent, if the known difference in tyrosine content of the purest isolated protein fraction was borne in mind. While the Kjeldahl analysis on sectioned strips would be satisfactory, the labour involved seemed to rule this out as a routine procedure. With widening experience the hope that the classical and paper-strip methods might be equated was diminishing. Clearly the technique of paper electrophoresis should, in future, stand alone.

Sensitivity and Resistance to Izoniazid

Prof. ROBERT KNOX said that strains of tubercle bacilli freshly isolated from the sputum of forty patients with pulmonary tuberculosis were found to be initially sensitive to isoniazid in a concentration of around 0·01 µg. per ml. by a tube-titration method in Dubos liquid medium. Standard conditions must be used because the end-point changed with prolonged incubation—partly because of deterioration of the drug, partly because of the development of resistance. In the course of treatment of a small series of patients with isoniazid resistant cultures developed very rapidly. The numbers of tubercle bacilli in the sputum showed a rapid decrease at first, followed by a reappearance associated with the development of resistance. The relation, however, between resistance in the test-tube and in the patient was not always clear. Compared with resistance to streptomycin, resistance to isoniazid seemed to be produced even more easily, at least in the laboratory; but it did not seem to reach the very high levels sometimes found with streptomycin-resistant organisms. Isoniazid-resistant organisms retained their sensitivity to streptomycin, and vice versa. On the other hand streptomycin appeared to delay the development of isoniazid resistance both in the laboratory and clinically.

Risk in Routine Tuberculosis Investigations

Dr. W. HOWARD HUGHES said that, in an attempt to assess the risk to the laboratory workers from the spilling of tubercle bacilli during the routine investigation of infected material, cultures were made regularly from the working site after the batch of work had been completed. The method used was to work in large enamel developing dishes lined with 'Cellophane.' and then to wash this and culture the centrifuged deposit. Results showed that the spluttering seen when wires were sterilised was of little importance, whereas pouring homogenised material from the original containers to 15 ml. centrifuge tubes was accompanied by heavy contamination. This spilling could be reduced, or eliminated entirely, by special care at this stage and by substituting 25 ml. wide-mouth bottles or 25 ml. centrifuge tubes for the smaller sizes. Change of staff or alteration of method always caused temporary increase of risk.

Renal Localisation of Ps. Pyocyanea

Dr. R. H. GORRILL had tested the pathogenicity of *Ps. pyocyanea* by injecting organisms intravenously into groups of white mice. It was found that with large numbers of organisms the mice died of septicæmia in one to two days. When the dose was lowered the mice survived the first two days and then died within the next fortnight of renal carbuncles. In all, twelve strains were tested; these were derived in equal numbers from wound and urinary tract infections, and the same results were obtained with them all. The earliest renal lesions, at twenty to twenty-six hours after injection of a suitable dose of *Ps. pyocyanea*, consisted of a focal embolic nephritis. After intravenous injection the blood became sterile in twelve to eighteen hours, and the lungs in twenty-four to forty-eight hours. The liver showed progressively fewer organisms throughout the experiment, but rarely became sterile. In the spleen the number remained about constant or fell; but the kidneys showed a progressive rise in bacterial count. It was suggested that, owing to its special anatomical and physiological properties, the kidney tended to filter out all types of particulate matter passing through it. When pathogenic bacteria like *Ps. pyocyanea* were filtered out they multiplied and rapidly attacked the kidney tissue, producing renal abscesses.

Physiological Variations in the Blood-count

Dr. JOHN MARKS (Cambridge) said that the value of a laboratory test depended on the accuracy of the method balanced against the range of physiological variation. In blood-counts venous blood gave lower results than capillary. Venous blood was used throughout. The factors mentioned were as follows:

Age.—Variations in age had no effect on the blood-count.

Sex.—The red-cell counts were well known to be lower, and the erythrocyte-sedimentation rate higher, in the female. The leucocyte-count was also significantly higher in females.

---

[3] Jensen, T. *Ann. Derm. Syph.* 1948, 8, 36. Stringer, H. W. C. Ph.D. Thesis, Edinburgh University, 1948. van der Lugt Personal communication, 1952.

Time of day.—The blood-count of both red and white cells was lowest in the early morning and rose to a maximum in the afternoon.

Exercise.—Even moderate exercise produced a rise in the leucocyte-count.

Environmental temperature.—During acclimatisation to heat there was a fall in the red-cell count. Exposure to cold caused a rise.

Menstruation.—No significant differences occurred during the various stages of the menstrual cycle.

Dr. Marks suggested that serial counts should be performed under "basal" conditions—i.e., in the early morning, with activity and temperature change restricted. He gave a set of basal normals.[3] This range was smaller than the "random" range for routine diagnostic counts on capillary or venous blood with the causes of variation not controlled. The values quoted differed from the accepted range.

Detection of Rhesus Antibody

Dr. K. L. G. Goldsmith said that papain is a proteolytic enzyme extracted from a plant called *Carica papaya*, or pawpaw. Like trypsin, it may be used to render a saline suspension of rhesus-positive cells agglutinable by incomplete rhesus antibody. The method he used was modified from a technique described by Kuhns and Bailey.[4] 650 maternal sera were examined and only two false-positive results were obtained, these both being due to cold agglutinins. Twenty-one sera containing rhesus antibody were examined, and in no case was agglutination absent when papain-treated cells were used. The antibody titre was noted, using saline, albumin, antiglobulin, trypsin, and papain techniques. In all cases the titre with the papain method was as high as, if not higher than, with the others. During tests with papain-treated red cells in other blood-grouping systems enhancement of agglutination was noted with anti-A, anti-B, anti-P, anti-M, anti-N, anti-Le^a, and anti-Le^b. No agglutination occurred with anti-Fy^a. Papain was readily obtainable, and cheaper than commercial bovine albumin or crystalline trypsin. Rouleaux formation was largely obviated, and the technique seemed to be as sensitive for routine use as any other yet available.

Hæmolytic Disease of the Newborn

Dr. J. F. Horley (Brighton) analysed a series of cases of hæmolytic disease of the newborn. Cases of artificially produced prematurity were not included. 83 cases of maternal rhesus sensitisation resulted in 11 stillbirths, 11 deaths (7 from kernicterus, 1 moribund at birth, 1 from alimentary hæmorrhage, 1 from heart-failure, 1 from pneumonia), and 61 living, including 9 rhesus-negative babies. The living babies were followed up and only 1—a case of neonatal kernicterus with permanent nervous sequelæ—was abnormal. The treatment used was conservative, the babies receiving transfusions only when their anæmia demanded it. By this method the cases were divided into two syndromes: one (82% in this series) a hæmolytic anæmia proportional in severity to the maternal antibody titre, adequately and simply treated along the lines indicated; the other, kernicterus. It was suggested that it was unsound to treat by exchange transfusion a series of cases in order to avoid kernicterus, and that as an alternative the babies should be allowed to declare themselves as belonging to one of the two groups and then be treated accordingly—the hæmolytic-anæmia group by simple transfusion, and the kernicteric group by exchange transfusion in the pre-kernicteric stage. In the absence of more specific tests, jaundice out of proportion to the hæmolytic process, as shown by the rate of fall of hæmoglobin, could be used as an indication for exchange transfusion. By this means babies with an excellent prognosis would not be endangered in trying to save those with a more uncertain outlook.

Reviews of Books

Housing and Family Life

J. M. Mackintosh, M.D., F.R.C.P., professor of public health, University of London. London: Cassell. 1952. Pp. 224. 16s.

For many years Professor Mackintosh has been keenly interested in housing, and in the relation between housing and health. His *Rural Housing* was based largely on conditions in Northamptonshire, where he was medical officer of health, and since that was published in 1935 he has seen at first hand the housing problems of Scotland, surely among the worst in Britain, and particularly the housing problems of Glasgow, undoubtedly the most grievous in Scotland. He has listened to the deliberations of those concerned with planning our new homes, and he has studied housing problems overseas, especially in Sweden and in America. He believes that the house—which has so much to do with the home—largely sets the standard of family life, and in this book he discusses the makings of the slum environment and the approach to rehousing. He pleads, as before, for more research and investigation: "So far we have not done nearly enough, and the houses are being built with all their sins upon them." Among non-material considerations, he thinks the first essential is to relieve overcrowding—one family, one dwelling—and the second to make the best use of the house as a whole by distributing family life intelligently within it. The chapter dealing with rehoused families adds something to our knowledge of the effects of housing on health, which—though we all feel it to be above question—still lacks overwhelming proof. This book will be widely read, with enjoyment and with profit.

Diary of a Psychiatrist

James T. Fisher, M.D., and Lowell S. Hawley. New York & London: Medical Publications Ltd. 1952. Pp. 256. 16s.

Dr. Fisher is a psychiatrist who has had a varied and interesting life, and this book is written by his collaborator, Mr. Hawley, as a series of loosely connected chapters of autobiography mingled with thinking aloud on divers medical topics in which the doctor, so to speak, lay on the analytic couch while his lay colleague took over the rôle of recording the flow of free associations. Unfortunately, we hear all too little of the doctor's life, which was interesting, enterprising, and original, and there are far too many of his reflections and opinions, which are none of these.

Dr. Fisher, who dictated this book in his 87th year, was raised on a ranch in Illinois at the whim of his wealthy father and received no formal education until he returned to the family home in Boston at the age of 13. He gained a lot by his early experience of life among animals and simple working people, and on his return to "civilisation" went through school and college and became first a veterinary surgeon and then a doctor. He decided to specialise in psychiatry, and made the first of numerous trips to Europe to meet and study under such authorities as Freud—without, it seems, being unduly impressed by the results of his travels. He then settled in Los Angeles and has practised there, apart from travels and service in both wars, as one of the leading psychiatrists and physicians of that region, at one time being assistant dean to the University of South California Medical School. The glimpses we get of the doctor's life and personality are tantalising, suggesting what a really interesting autobiography Mr. Hawley had on his line.

Tubercle Bacillus and Laboratory Methods in Tuberculosis

M. A. Soltys, PH.D., lecturer in bacteriology, school of veterinary science, University of Liverpool; C. A. St. Hill, M.B., consultant pathologist, Royal Southern Hospital, Liverpool; I. Ansell, M.D., M.R.C.P., consultant physician, Liverpool Chest Hospital. Edinburgh: E. & S. Livingstone. 1952. Pp. 212. 20s.

Research on tuberculosis flourishes so profusely that a periodic pruning of the side-shoots is necessary if the casual observer is to inspect the main stem and its important branches. This book gives a useful account of modern work. Part I deals with the morphology and chemical and antigenic structure of *Mycobacterium tuberculosis*, as well as the cultural characters, metabolism, and virulence of the organism. The second, and much longer, part describes laboratory methods of diagnosis, together with chapters on tuberculin and chemotherapy. The unwary reader might infer that great progress had recently been made in the means of demonstrating the organism or isolating it from patients, but this is not so; and though the various methods of concentrating tubercle bacilli are described in detail, a fully satisfactory work on this subject has yet to be written. Greater prominence might have been given both to the non-pathogenic acid-fast organisms which can readily be confused with *Myco. tuberculosis*, and to pseudotuberculosis of the guineapig.

Architecture of Normal and Malformed Hearts

ALEXANDER SPITZER, late professor of anatomy, University of Vienna. With a summary and analysis of the theory by MAURICE LEV, M.D., associate professor of pathology, University of Illinois College of Medicine, and ALOYSIUS VASS, M.D. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1951. Pp. 145. *36s.*

IN 1923 Alexander Spitzer, professor of anatomy in Vienna, put forward a phylogenetic theory of the development of the heart, and on this basis endeavoured to explain most of the malformations commonly encountered. This theory has not received wide notice, nor has it been extensively accepted, but the authors have tried to clarify an extremely complicated German article and to elaborate it with criticisms and comments of their own.

The basis of Spitzer's theory is that the mammalian heart possesses certain atavistic structures which are only present as rudiments. He postulates that hydrodynamic factors, such as blood-volume and blood-pressure, play an important part in alteration of structure, and shows how in mammals the development of the pulmonary circuit leads to a change from the single circulation, as found in a fish, to a double one. A two-sided heart must evolve from a one-sided or single one; and the sides should be, to use electrical terms, in parallel though functioning in series. Division of the heart by a straight septum would produce the parallel system but not one which works in series where the blood from one side is returned to the other side. The complicated torsions of the heart-tube and developing septums are in part influenced by the pulmonary circulation. The development of this torsion and extension of rudimentary structures has been used to explain such abnormalities as transposition of the great vessels.

Though this short monograph aims at simplification it is not written in an easy style.

Guide to Filter Paper and Cellulose Powder Chromatography

J. N. BALSTON, B.A., and B. E. TALBOT. London: H. Reeve Angel. 1952. Pp. 148. *8s.*

MANY analytical operations on the micro scale can nowadays be performed by chromatographic methods, accurate and simple, which have displaced many older and much more cumbersome techniques. As our knowledge of cellulose chromatography widens every day, it is no fault of the authors that their work is not "up to the minute." Nevertheless, this is a valuable work containing over 550 references, nearly all dated between 1949 and 1951. Methods and materials are considered in one section and applications to various types of analyses in another. Workers in both routine and research laboratories will find this well-indexed book of great assistance.

Health and Agriculture in China

A Fundamental Approach to Some of the Problems of World Hunger. JAMES CAMERON SCOTT, M.A., B.SC., formerly professor of soil science, Cheeloo University, North China. London: Faber & Faber. 1952. Pp. 279. *25s.*

THE author of this work was formerly a member of a research team at Cheeloo University engaged in a study of agricultural sanitation from 1935 to 1941. Chinese farming depends on the use of human fæces as a fertiliser on a vast scale (an estimate in 1924 put the annual value of the manurial output of the Chinese people between £50 million and £80 million). How this fertiliser can be most efficiently collected, prepared, stored, and utilised, and how, at the same time, fæcal-borne diseases can be controlled, is the theme of the book. The problem is never simple, and Professor Scott makes it clear that the investigations which he describes have raised more questions than have been answered. But the questions he raises are practical and demand a scientific solution, if the people of China are ever to enjoy reasonable health. He was sent to China by the Baptist Missionary Society, and much of the expense of the investigation was borne by the Rockefeller Foundation. It is one of the tragedies of our time that humane scientific work can no longer be carried out in China by great organisations such as these.

The book is written simply for the general reader, but the expert sanitarian will find plenty to consider, and each chapter has a full list of references.

Essentials of Neurosurgery

LESLIE C. OLIVER, F.R.C.S., neurosurgeon, West End Hospital for Nervous Diseases, London. London: H. K. Lewis. 1952. Pp. 256. *25s.*

IN just under 200 pages Mr. Oliver has provided a short account of neurosurgery which should prove useful to students reading for higher degrees. The section on cerebral tumours particularly will repay study. It is disappointing, however, to find that the book is not well balanced; a disproportionate amount of space has been given to some neurosurgical topics which could have been better devoted to commoner conditions, and this will limit its appeal as a general introduction to the subject. There are 50 illustrations, but some of the radiographs are poorly defined.

British Dental Annual 1952

Editor: EVELYN SPRAWSON, M.C., D.SC., F.D.S., M.R.C.S. London: Butterworth. 1952. Pp. 262. *35s.*

THE original articles which make up two-thirds of this book are all of high quality. A useful article describes the public dental service, its history, development and present position, and discusses its future. But more space might well have been given to advances with which the dentist must keep abreast to maintain his professional efficiency, and illustrations of operative techniques would be a welcome addition to the next issue.

Current Therapy (Philadelphia and London: W. B. Saunders. 1952. Pp. 849. *55s.*).—The editor-in-chief, Dr. Howard F. Conn, has again cast his net widely; there are over 350 contributors to this massive American annual, of whom 189 are making their debut in this year's edition. Moreover, the book goes far beyond the purely medical conditions, and tackles, for instance, acute appendicitis and ectopic pregnancy. Spectacularly complete and helpfully concise, it maintains its place as a reference work of the first class.

Tuberculosis of Bone and Joint (2nd ed. London: Oxford University Press. 1952. Pp. 314. *45s.*).—In the first edition of this book the late Prof. G. R. Girdlestone did not set out to write a compendium of treatments of tuberculous disease of bones and joints as practised in the British Isles, but rather to describe well-tried methods based on the teachings of Robert Jones with the addition of his own long personal experience and the methods developed at the Wingfield-Morris Orthopædic Hospital. In addition to treatment, there were chapters on general diagnosis of bone and joint tuberculosis, and in regional chapters differential diagnosis was discussed. In this second edition, in which he had the assistance of Mr. E. W. Somerville, F.R.C.S.E., the general scheme has remained unchanged but there have been additions and minor alterations. These include an outline of chemotherapy in tuberculous disease, and references to compression arthrodesis of the knee and to anterolateral and lateral spinal decompression in Pott's paraplegia. There is now a very useful appendix on splints and appliances commonly used in the treatment of this disease. Throughout the book stress on the importance of general treatment and the established methods of local treatment balances the emphasis nowadays laid on chemotherapy. More space and detail might have been given to some of the advances which have proved valuable since the publication of the first edition. Nevertheless this remains a good straightforward textbook on the diagnosis and treatment of bone and joint tuberculosis as practised in the British Isles.

THE LANCET

LONDON: SATURDAY, OCT. 18, 1952

Frozen Storage for Red Cells

Freezing in glycerol has been used for many years as a method of preserving viruses; and three years ago Polge et al.[1] found that spermatozoa could be similarly preserved and retain functional activity. Red blood-cells stored by the usual methods at about 4°C can be kept for only four weeks at the most; and for this reason a team of workers at the National Institute for Medical Research have been examining the possibilities of preserving red cells by freezing techniques.

In 1950 Dr. Audrey Smith[2] showed that red blood-cells could be preserved in the frozen state if suspended in a mixture containing 10–15% glycerol. She carried out experiments with heparinised rabbit blood diluted with an equal part of a glycerol-Ringer solution. In low concentrations glycerol is hæmolytic, but at higher concentrations there was no trouble from this effect. The blood-glycerol mixture was quickly frozen to −79°C (the temperature of a solid carbon dioxide and alcohol mixture) and stored at this temperature. On subsequent thawing at 40°C most of the red cells were found to have survived and to be of normal shape after various periods of storage up to three months. Similar treatment given to red cells diluted only with Ringer solution without glycerol resulted in almost complete hæmolysis. Sloviter,[3] continuing this work with human red cells, found that these could also be recovered after freezing and storage in a 15% glycerol-saline mixture; but when the cells were resuspended in plasma, hæmolysis occurred rapidly because the glycerol in the cells attracted water into the cells so that they quickly swelled until they burst. To get over this difficulty the thawed mixture was dialysed in a sausage-skin tube against saline containing diminishing proportions of glycerol, and finally against isotonic saline alone. Even this did not give really good survival, and it proved necessary to begin the procedure by allowing the mixture of blood and glycerol-saline to stand at 5°C for one to two hours before freezing. With these methods Sloviter recovered 79–94% of the red cells, and these recovered cells were shown to have a normal resistance to hypotonic saline. The next step[4] was to take rabbit red cells that had been kept at −79°C for up to forty-two days and then, after thawing and recovery, to mark them with radioactive phosphorus (P^{32}). These marked cells were transfused into rabbits, and it was shown that frozen and thawed cells were as viable as marked red cells that had not been so treated. These experiments only covered a few days, because of the short half-life of P^{32}.

Mollison and Sloviter[5] carried out the same sort of experiment with human red blood-cells. They devised a suitable technique for freezing to −79°C a volume of 500 ml. of red cells mixed with 15% glycerol-saline and for recovering the red cells freed from glycerol after thawing. Their method gave on the average about 70% recovery of red cells. As sterility had to be maintained throughout, the technique was somewhat elaborate. The red cells were kept frozen for only two to three hours before thawing; but before the recovered cells were transfused sterility had to be ensured by cultures, and this involved a delay of seven days during which the blood was kept at the usual 4°C. Blood of group A N Rh-positive was used for freezing, and blood of group O M Rh-positive drawn at the same time and stored throughout at 4°C was used for control. These bloods were transfused into group A M Rh-positive recipients, and the survival of the transfused red cells was followed by the Ashby technique of differential agglutination. The results of two such survival experiments suggested that there was little difference in viability between the frozen and thawed cells and the cells that had been kept at 4°C. For instance, in one experiment after twenty-four hours 86% of the control red cells were present and 76% of the frozen cells; sixty-seven days after the transfusion 37% of the control cells and 33% of the previously frozen cells were still there. A few months ago Sloviter[6] reported that human red cells had been frozen, stored at −79°C for up to nine months, and then satisfactorily recovered after thawing. The percentage of recoverable cells dropped during storage. For example, after one day of storage 90% of the cells were recovered, after one month 80%, and after six months 70%; but at nine months the recovery-rate was still about 70%. Last month Mollison et al.[7] described results obtained when red cells that had been kept in the frozen state for nine months were thawed, freed from glycerol, and transfused into suitable recipients. The same technique was used as that for cells frozen for a few hours. The survival of the long-frozen red cells was compared with the survival of red cells stored at 4°C for eleven days, because the preliminary stages before freezing, and delays while sterility was confirmed after thawing, meant that the red cells were kept at 4°C for about eleven days. Results with five transfusions showed that the cells stored for nine months in the frozen state had the same order of viability as the cells that had not been frozen at all. They also showed that storage at only −15°C also preserves red cells in a viable state, but a large proportion of cells stored at this relatively high temperature are lost by hæmolysis during the recovery process; consequently −79°C remains at present the recommended temperature for storage.

7. Mollison, P. L., Sloviter, H. A., Clapham, H. *Lancet*, Sept. 13, 1952, p. 501.

It has thus been established that human red cells can be suspended in a 15% glycerol-saline solution, frozen to −79°C, recovered after up to nine months, and still be suitable for transfusion purposes. There are, however, still two practical difficulties about applying this knowledge on a large scale: it takes quite a lot of effort to deal with 500 ml. of mixture (equivalent to only 250 ml. of red cells); and the technique of freeing the thawed mixture from glycerol by dialysis in a sausage-skin, maintaining sterility at all times, is particularly limiting. Lovelock[8] has described an alternative technique that may help because it does not use dialysis. He adds to the newly thawed mixture of red cells, glycerol, and saline a substance that will raise the osmotic pressure of the suspending medium, but to which red cells are relatively impermeable; sodium citrate in a concentration of 0·33 *M* or glucose 1·0 *M* are suitable. After the addition of citrate or glucose the temperature of the mixture is raised to 20°C and the glycerol escapes from the red cells in about five minutes. The cells can then be separated by centrifuging and resuspended directly in isotonic saline or plasma. The other practical difficulty is that the recovery-rate of red cells after being frozen and kept for nine months is on the average only 70% and may, in individual samples, be as low as 50%. This is too large a loss for the method to be of practical use. Further research is going on and this obstacle is likely to be overcome.

If the technical difficulties, particularly those of reconstitution, can be solved, it will be very useful to be able to store red cells more or less indefinitely, and much waste could thus be avoided. If the antigenic properties of red cells also survive this treatment, red cells of rare groups could be stored for reference. Another practical problem that has to be faced is whether red cells suspended in saline are an adequate substitute for the concentrated red cells so much used nowadays in the treatment of anæmia. For the treatment of shock whole blood is important, and preserved red cells would have to be suspended in plasma or possibly in a transfusion substitute like dextran. These points are all likely to have the attention of the Medical Research Council team.

Polypoid Growths of the Intestine

Polypoid growths of the intestine are not very common, yet they have great interest and importance in surgical practice. Whenever such a growth is found the possibility of multiple growths and of malignancy has to be considered. The problem may present itself in several ways. Almost one might say that polyp formation in the intestine causes three types of disease. In one the surgeon removes a single rectal polyp, and he has to decide, with the guidance of the pathologist, whether this is benign or shows a low or high degree of malignancy, and thus whether he has probably cured his patient by a limited operation. In quite a different category is the patient whose repeated attacks of intestinal colic draw attention to multiple polypi of the small and large intestine which are causing recurrent intussusceptions. This is the familial disease associated with facial pigmentation described recently in our columns by Dr. Wolff[1] and Professor Basu.[2] Finally, there is the rare familial intestinal polyposis in which cancer of the rectum arises with great frequency and at an exceptionally early age. The hereditary factor in this disease has been very convincingly demonstrated by Cuthbert Dukes,[3] who has shown that polyposis is inherited as if it were a mendelian dominant.

On another page of this issue, Mr. Lockhart-Mummery and Dr. Dukes discuss the surgical treatment of the single malignant rectal polyp. Such polyps are often removed locally without a preoperative diagnosis of malignancy. A report from the pathologist of malignant change limited to the mucosa means that the grade of malignancy is unlikely to be high; anaplastic carcinoma of the rectum tends to grow rapidly, soon invading the deeper tissues. Patients with such limited growths have done well with local excision, and Lockhart-Mummery and Dukes conclude that this suffices. The after-history of patients who had local excision of polyps in which carcinoma cells had already invaded the stroma or submucosa varied with two factors: (1) the grade of malignancy, as determined histologically; and (2) the extent, if any, of the free margin of tissue removed beyond the growth. Cases of "invasive" carcinoma in which the grade of malignancy was low also did well with complete local excision. Lockhart-Mummery and Dukes say that lymphatic spread in these cases is improbable, and a local recurrence is within easy reach of further operation. With high malignancy or removal of insufficient margin, the growth tends to recur; and a histological report suggesting either of these states should be followed by radical surgery. With these views American workers are in substantial agreement. Sandusky and Parsons[4] voice the general perplexity about the correct treatment of the rectal polyp first excised and then found to be malignant. Dr. Frank Lahey, in discussing their paper, mentioned another very pertinent point when he described the dilemma of the surgeon who at laparotomy fails to find a polyp he knows to be present in the colon. American surgeons seem to agree that where the diagnosis of cancer rests solely on microscopic evidence, there is no invasion of the deep tissues, and the whole polyp has been removed, one may safely forgo radical surgery.[5][6] American surgeons, while acknowledging the importance of close coöperation between the surgeon and the pathologist in decisions on treatment, do not seem to pay much attention to the grading of tumours. Here we feel that Dukes's experience that grading provides a valuable guide deserves careful consideration.

Familial polyposis of the large gut presents a much more complicated problem. The patient most often comes with a history of diarrhœa and bleeding—possibly with a provisional diagnosis of "colitis." Sigmoidoscopy reveals the extensive disease of the rectum and colon. The family history may include accounts of other patients with a similar history.

Since J. P. LOCKHART-MUMMERY,[7] then senior surgeon to St. Mark's Hospital described in these columns in 1925 the history of three polyposis families, the hospital has made a special study of the hereditary aspect of intestinal polyposis and now has records of 22 families with more than one member affected. In these 22 families, there are 407 members the state of whose health is known. 133 are known to have developed polyposis, and in 99 of these polyposis has eventually been followed by cancer of the rectum or colon. This gives an incidence of 32·6% for polyposis, and of 24·3% for cancer. The incidence is really higher, for the onset of polyposis is unusual before the age of 10 years, and the average age at onset is 20 years; carcinoma develops about 15 years after the start of polyposis. Some members of the families under observation are too young to have developed the disease. DUKES[8] concludes that in most polyposis families half the children are likely to inherit the abnormality. As a rule, only those who inherit the disease transmit it to the next generation; but it can be transmitted by either males or females, and either sex can be affected.

Polyposis is not a disease in which several isolated tumours appear in otherwise healthy mucosa. The mucosa is almost carpeted with tiny adenomata formed by excessive proliferation of the glandular epithelium of the rectum and colon; in places these adenomata are large enough to be described as tumours. As months or years go by, one or more of the tumours becomes malignant. Symptoms vary in severity, and may remain insignificant for many years after the known onset of polyposis. Treatment is a matter of grave concern and of great difficulty. The polyposis patient is safe only without his colon. In the presence of carcinoma the operation should be very radical—even to the extent of complete colectomy, leaving the patient with an ileostomy. Non-malignant cases may be treated by a combination of endoscopic diathermy and subtotal colectomy, with anastomosis of the ileum to the rectum. Local recurrence of polyposis in the rectal mucosa can be treated by repetition of diathermy. DUKES[8] considers that milder cases can be kept under control by periodic endoscopic diathermy without radical treatment.

Two cases of the rare familial disease in which multiple polypi of the small, and possibly of the large, intestine are associated with congenital pigmentation of the skin and mucous membrane of the face, have been reported in our columns. WOLFF,[1] who recorded one of these cases, referred to 26 previous records. Attention is drawn to the syndrome by repeated attacks of small-intestine obstruction, caused either by a large polyp or by intussusception. The incidence of carcinoma is very low. In affected families pigmentation may occur in some members without abdominal symptoms. At operation, which may be an emergency procedure, the surgeon has to decide which polyps to remove and which to leave. Recurrence of symptoms is all too likely. This is a rare disease, but attacks of abdominal pain in a patient with dark pigmentation of the lips and mouth who does not have Addison's disease should, in WOLFF's opinion, arouse strong suspicion of polyposis of the small intestine.

Age and Earning

LIKE guests afraid of outstaying their welcome, those over and approaching 65 are developing an alert look. What is the proper move, how shall they avoid a gaffe? Only a few years ago it would have been right to retire, to make way for the young ones, to relieve unemployment by accepting their old-age pensions, and to die early, if need be, of boredom. Now, it seems, it is their duty to keep going, to stave off senescence with work, and to postpone drawing their pensions as long as possible; but to make way for the young ones, all the same, by stepping down from the top jobs. At any moment, they feel their hosts, in the productive years, may say brightly: "It's *lovely* to have you with us, of course, but there *are* rather a lot of you, aren't there, ha ha ha? And not too many of us to hand round the cake." There is even some danger, as three Conservative Members of Parliament hint in a recent pamphlet,[1] of a political conflict between the young and the old. Indeed, they seem to be doing a little towards promoting the conflict themselves, by presenting one aspect of the case incompletely. "Today," they say on their first page, "there are more than $5^{1}/_{4}$ million old people in the country, representing 11% of the population: for every old person there are now only six of working age. In twenty-five years' time the number will have soared to $8^{1}/_{4}$ million men and women over the age of 65—no less than 16% of the population. For every old person there will be only four people of working age." The fact is, of course, that those in the productive years have to maintain *all* the non-producers—the young as well as the old; and while the old have been increasing, the ranks of those under 15 have thinned. In 1901 37% of the population were in the non-productive age-groups, so there were less than two producers to work for each of them. By 1944 the non-producers (despite the increase of old people) had fallen to 30%. Careful forecasts suggest that even in fifty years' time the aged will not have increased beyond 18% of the population, while the young will account for only about 16%—a total of 34% in the non-productive age-groups. The producers will still be less burdened than their forerunners of 1901, and indeed will not be much worse off than their counterparts of today. Since the numbers of the old cannot exceed a fixed upper limit, the only thing which could change the picture for the worse (as far as producers are concerned) would be a phenomenal rise in the birth-rate.

But of course the whole theory of "non-productive age-groups" is a convenient fiction. In COBBETT's time, as we all know, children over the age of four could usually be classed as producers. In our own day the 15-year-olds have recently joined the non-producers, and another large group will be added when the school-leaving age goes up to 16. There is not the least reason for assuming that every man over 65 and every woman over 60 would be the better for not working any more. In the case of women the assumption is particularly odd, since more of them live longer, and most of them are more active and enterprising in old age, than men. But, as the writers of the pamphlet point out, the idea of retirement at 65 or 60 is now ingrained in the nation, among both employers and employees. Some employers impose early retirement in their superannuation schemes, and are reluctant to engage anyone in the middle or later years. Of the present unemployed most are over 40, and unemployment is twice as common among those over 50 as among the population as a a whole. Certainly people in every walk of life are well aware of a prejudice against the employment of older men and women. The reasons most employers give for this reluctance, the pamphlet says, are a wish to promote younger people, unwillingness to adapt employment policies to an era of full employment, unwillingness to find suitable tasks for the old, and difficulties with superannuation schemes. Moreover, many employees regard retirement at a given age as a right. All the same, 46% of men aged 65–70, and 10% of women aged 60–65 stay on at work, and more might do so with encouragement.

[1] The Care of Old People. By KENNETH THOMPSON, JOHN VAUGHAN-MORGAN, and ANGUS MAUDE. Conservative Political Centre Discussion Series. Pp. 30. 6*d*.

At present the "earnings rule," which limits the pensioner's additional earnings to £2 a week, is a serious deterrent. The scale of increments to pensions, for remaining at work longer, is perhaps not sufficiently attractive; and there are some who wish to go on working but cannot find the work. Again, some could go on with their jobs after retiring age if they worked fewer hours; but they cannot live on the reduced pay they would then earn. Some, having tried retirement, do not like it, and might come back to work if the new spell of employment increased the final pension. The writers of the pamphlet believe we might attract a great many seasonal workers if every 25 stamps, however long it took to collect them, counted towards an increment. Again, a large source of labour might be tapped by making a sliding-scale reduction in pensions for those undertaking half-time or part-time work. Employers, too, might well spend more thought on providing appropriate jobs and sheltered workshops for those who need a gentler pace. The skills of the aged are by no means negligible. Apart from the elderly of the professional, technical, and administrative classes, who can put a great fund of knowledge and experience at the disposal of the nation, there are all the skilled craftsmen, many of whom are already kept on by their employers. But even the rank and file of the elderly, it seems, have an accuracy and reliability not so common in the young; and they are often capable of being trained in new work, especially if it uses old skills.[2]

These writers recognise that the proper care of the elderly includes more than the adequate treatment of their disorders when these arise: the resources of social medicine can do much to preserve their health, improve their nutrition, and enable them to keep their independence. Nowadays, as Mr. JOHN A. OLIVER, PH.D., has recently pointed out,[3] it is generally agreed that the proper place for old people is in their own homes, and this pamphlet, too, advocates the humane and economic policy of helping them to stay there. Many local authorities now build special cottages for old people on their housing estates, but few build enough of them. The writers quote the experience of Hornsey Borough Council, who built 34 cottages for old people, and found when the tenants moved in that they had released 6 houses with six rooms, 22 houses with four or five rooms, and 4 houses with three rooms—277 rooms in all. Even some old people living with married children would be glad of a small home of their own. The burden of the old on the young has often been aired: this pamphlet refreshingly mentions the burden of the young on the old. The patter of little and not-so-little feet is not everybody's idea of a delightful accompaniment to a swan song.

On the question of medical care for the old the writers are cautious—as they may well be in dealing with so confused a topic. They note the lack of beds for the elderly, but recognise that the demand for beds could be much reduced by more preventive care for the old, more residential homes, and more "half-way" convalescent homes. It is difficult, they say, to develop this last type of institution while the responsibility for maintenance cannot be exactly fixed between the local authorities, the National Health Service, and the National Assistance Board. All the same, one institution of the kind has been started—Springbok House at Stanmore, set up by the National Corporation for the Care of Old People. The experience gained there is bound to be valuable. The prognosis of the pamphleteers, that perhaps "such problems cannot be finally settled while local government areas and hospital areas differ," seems hardly justified; though things would certainly be simpler if these territories were conterminous.

Annotations

PULMONARY COMPLICATIONS OF INFLUENZA

BY all the rules, there should be no large epidemic of influenza A in the coming winter; but the rules are often broken, as the sharp Liverpool outbreak in 1951 showed. The general practitioners, who have to deal with both the sheer mass of sickness and the pulmonary complications that call for special treatment, face the hard task of distinguishing those patients who are likely to need admission to hospital and urgent chemotherapy from the many who can be safely left in their homes. This task involves the recognition of severe influenzal pneumonia at an early stage, before the onset of the rapid deterioration that sometimes occurs. Unfortunately, the clinical picture of influenzal pneumonia is not as clear-cut as some descriptions suggest, and the doctor is in fact confronted by a whole range of patients with various forms of chest complication, many of which will respond well to the up-to-date treatment for bronchopneumonia or lobar pneumonia. Indeed, some people doubt whether influenzal pneumonia is a distinct entity, differing clinically from other forms of pneumonia, though Scadding[1] thought that it was.

Tyrrell[2] has now reopened the question by making a detailed analysis of the chest complications of influenza. His results justify the continued use of the name "influenzal pneumonia," but they underline the difficulty of recognising such cases clinically. Before the epidemic of influenza A in Sheffield in March, 1949,[3] Tyrrell examined a number of patients with bronchitis, and others with bronchopneumonia or lobar pneumonia, who were admitted to hospital for treatment and were found to show no serological evidence of infection with influenza virus. His work began at the time described by Bradley[4] as the influenzal nadir of 1948, and in many cases the illness had a sudden onset, with definite signs of lobar pneumonia. Some patients had had chronic chest disease in the past, but the response to chemotherapy was good, and only 2 patients died.

[2] Tyrrell, D. A. J. *Ibid*, 1952, 21, 291.

[3] Stuart-Harris, C. H., Laird, J., Tyrrell, D. A., Kelsall, M. H. Franks, Z. C. *J. Hyg., Camb.* 1949, 47, 434.

His second group included patients who were admitted during or after the epidemic of influenza A and who were found to have infections of the lower respiratory tract, including bronchitis or pneumonia. Some were proved to have influenza-virus infections, either by serological tests or by isolation of the virus, and others gave serological evidence of influenzal infection before the onset of the pneumonia. Tyrrell noted two groups of influenzal cases that could be recognised clinically—those with severe tracheobronchitis, and those with fulminating staphylococcal pneumonia. The other forms of pneumonia seemed more severe than those seen before the epidemic, and more patients died. Moreover, in the pneumonias associated with influenza-virus infection, mental changes, cyanosis, and widespread râles and rhonchi outside the area of consolidation were commoner than in the non-influenzal cases. Chemotherapy was less effective in the influenzal cases, as judged both by mortality and by the time taken for the fever to subside.

This work emphasises how necessary it is to give particular care, during an influenza epidemic, to patients with chronic bronchitis or pre-existing heart-failure, and also to old people. The rapid deterioration, intense dyspnœa and cyanosis, and bloody sputum of staphylococcal pneumonia distinguish this most dangerous form of chest complication, which must be continually borne in mind if it is to be recognised quickly.

The way in which the influenza virus alters the clinical picture of bacterial infection of the lungs was not dealt with in this investigation. Harford and Hara[5] found evidence in mice to suggest that the œdema caused by the influenza virus facilitates invasion of the lung by pneumococci. Moreover, the tracheobronchitis of virus infection can cause mucus plugs to form in the bronchi and areas of collapse to develop in the lungs. Yet, as others have shown,[6] many less extensive lung changes may take place in influenza, some resembling atypical pneumonia; but these are fortunately benign and hardly enter into the clinical diagnosis. Now that more outbreaks of influenza are being investigated by clinical and laboratory methods, two facts are beginning to stand out: the staphylococcus is the bacterium to fear in the sputum; and the virus itself is certainly closely concerned with the increased severity and mortality of pneumonia during an epidemic.

MORE HERESY

Dr. Adrianus Pijper of Pretoria is a heretic, and it is fortunate for him that he studies microbiology in the 20th century and not theology in the 4th. We have on several occasions mentioned his view that the bacterial flagellum is the consequence, and not the organ, of progression; and if this unorthodoxy has had no other merit it has been the stimulus to many elegant and interesting experiments designed for its refutation. His latest communication[7] concerns a less outrageous denial of established belief but will, we hope, have the same result.

Many of us have seen the iridescent sheen on a confluent culture of bacteria held obliquely to the light, and most have accepted it without much thought of its cause. Many years ago Pijper[8] guessed that such a thin film of bacteria might act as a diffraction grating, so that the diameter of the spectral halo thrown on a screen by a beam of light passing through the bacterial film would bear an inverse ratio to the size of the bacteria making up the film. The principle is not new; it was first devised by Thomas Young, physician to St. George's Hospital (in the intervals of describing his modulus and deciphering the Rosetta stone) as an aid to classifying wool fibres. Pijper's attention was diverted to the use of this device, the "halometer," for measuring the diameter of red blood-cells; and older hæmatologists will bear witness to its value before the more informative hæmatocrit came into use. That happened thirty years ago, and now he has given some further observations on this method. It measures the diameter of cocci and the breadth of bacilli, and such measurements are better expressed in relative than absolute values. If the breadth of *Salmonella typhi* be given a value 1·0, *S. paratyphi B* is found to give a figure of 0·94 and members of the coli-aerogenes group figures ranging from 1·08 to 1·38. These are constant for each species, provided it is measured at the same stage in the growth cycle.

Since species differ in their least dimension, might they not be separated by differential filtration? If a barrier of sterile sand be placed in the loop of a U-tube filled with nutrient broth and if a mixture of organisms including *S. typhi* be added to one limb, this species is usually the first that can be recovered from the other side of the sand. But sand is awkward stuff to handle, and a "fairly tight" plug of cotton-wool in a Craigie tube gave more consistent results. All organisms will of course find their way through the obstruction in time, and the medium on the "arrival side" must be subcultured at short intervals if *S. typhi* is to be found in pure culture. Anomalous results revealed some interesting antagonisms between species. *Brucella abortus* penetrated the barrier quicker than staphylococci, but when cultures of the two were mixed the brucella never came through the barrier at all. Suspended in saline, however, it won every time. Similarly *S. typhi* died in the presence of *Bact. cloacæ*; but when the experiment was performed in Wilson and Blair's liquid medium it was possible to plant these species in a ratio of 1 : 100,000, and yet *S. typhi* came through the barrier first. Thin bacteria not only get through the fence quicker than the fat, but they ascend higher on a strip of filter-paper dipped in a bacterial mixture. *S. typhi* reached an altitude of 4.1 cm., while *Bacillus anthracis* could get no higher than 1·1 cm. and the obese sarcina stopped even lower. Others have noticed this phenomenon and have given diverse explanations. Motility, electrical charges, and "wettability" have all been suggested; but Pijper contents himself with the idea that to climb through the hairy pores of filter-paper may entail the same troubles as pushing through a barrier of cotton-wool.

Some of these observations are not entirely novel. Attempts to put them to a useful purpose have been made in the past; and as a result of this paper they will no doubt be made again. But we are better pleased to see how far uninhibited curiosity has led an inquiring mind in thirty years. Once again Pijper will set many of his colleagues observing and experimenting—and probably contradicting—and for this alone he will deserve well of them. We hope he will be careful. He may read of the penalties of heresy in Gibbon; and we have heard rumours that there are places even today where scientific unorthodoxy is curbed with almost byzantine ferocity.

THE INEXPANSIBLE LUNG

THE recent decline in the death-rate from tuberculosis has not been matched by a corresponding decline in its morbidity. As Daniels[1] points out, the advent of streptomycin and the advances of chest surgery have prolonged the lives of many patients who would otherwise have died in a year or two. The increasing number of these long-standing cases throws into relief the problems of the late results of treatment in pulmonary tuberculosis. One of these difficulties is the inexpansible lung, to which attention has lately been directed by Jackson.[2] Ten years ago Farber[3] estimated that in 5% of patients who have had an artificial pneumothorax there is a persistent pleural dead space. Jackson noted that in two wards at Clare Hall Hospital there were 11 out of 70 patients in whom the inexpansible lung had become an important factor in determining the course of the disease and its treatment.

It is difficult to define the term inexpansible lung. Jackson uses it to include any condition in which a pleural dead space persists, whether the space is filled by air, fluid, fibrin, pus, blood-clot, or a combination of these. Nature tends eventually to obliterate this space by mediastinal shift, falling in of the chest wall, elevation of the diaphragm, and compensatory emphysema with occasional herniation of the contralateral lung. The sum of these compensatory mechanisms he calls "false expansion."

The functional results of a persistent pleural dead space and of false expansion are the same, and in such cases Pinner et al.[4] found that the patient is lucky if he keeps 50% of normal function in the affected lung. Very often the functional capacity of the inexpansible lung is negligible. If the process is bilateral it is easy for the patient to become a respiratory cripple, and he may die from pulmonary heart-failure rather than tuberculosis. Dragging chest pain, dyspnœa, and palpitations are common symptoms in the milder cases. In addition, where fluid persists there is the constant danger of empyema. The encasing of the lung in a rigid thick fibrotic pleura may, paradoxically, prevent selective collapse, and, particularly if there is much associated bronchial tuberculosis, it may do nothing to prevent the continued activity of the disease.

An inexpansible lung is almost always the aftermath of an effusion, which may be quite small at first. Collapse or bronchopleural fistula often determines the onset of the effusion. Once established the condition is difficult to treat. When a pneumothorax has been induced, attempts to refill it may be continued indefinitely, but this is seldom profitable. False re-expansion may be allowed to occur at the risk of producing a respiratory cripple, or of lighting up quiescent disease in the over-distended contralateral lung. Oleothorax was invented to deal with this problem, but its use has been generally abandoned. Phrenic crush provides another method of obliterating the dead space, but it is apt to prove a two-edged weapon. Thoracoplasty, if undertaken for these cases, must be very extensive, and pockets of fluid are liable to give trouble. Pneumonectomy is needed when infection smoulders in a shrunken fibrotic lung, and especially when there is associated endobronchial disease. Decortication has its advocates, but it can only restore function if performed before pleural thickening has become too extensive. Plombage, in which the dead space is filled by packing some neutral substance outside the pleura, is another alternative. But the best treatment is prophylactic. Stricter selection of cases for artificial pneumothorax is desirable, and chest physicians are becoming increasingly aware of this. Jackson goes so far as to advocate routine bronchoscopy before the induction of any artificial pneumothorax in order to avoid the atelectasis and its sequelæ that may result from tuberculous bronchitis. In the patient who shows a tendency to thickening of the pleura, it is wise to keep the pneumothorax as shallow as possible, and there is a danger in maintaining even a good artificial pneumothorax for too long. Perhaps three years is long enough in the majority of cases. In patients with a primary tuberculous pleural effusion, the tragic complication of a "frozen chest" might become less common if aspiration was performed more often. In any case the dangers of the inexpansible lung must be weighed against the dangers of too early re-expansion of a well-collapsed lung, and the decision will continue to tax the skill and judgment of the chest physician as it has done in the past.

EFFECTS OF LEUCOTOMY

PSYCHOLOGISTS have so far been of little help in unravelling the changes observed by the clinician after the operation of prefrontal leucotomy in mental illness or in cases of intractable pain. One of the reasons for their lack of success was the obvious difficulty in testing psychotic patients before operation, for comparison with later tests. Mrs. Petrie[1] reports test results in 50 cases of neurosis treated in the psychiatric department of St. George's Hospital, London. As their mental function was comparatively little impaired, and as the patients coöperated well from the start, a clearer and less equivocal picture was to be expected than in any psychotic group. Moreover, two different operations were used, besides the standard coronal cut which was carried out in the majority of patients.

The tests used were those of H. J. Eysenck; and Mrs. Petrie's psychological views, as well as her painstaking treatment of figures, are what one would expect from a worker trained in the Maudsley department of psychology. While the care and industry of the work is impressive, and the presentation is lucid, the results are disappointing because almost nothing was found that has not been described before by numerous observers: for example, reduced "neuroticism" (which here can only mean some clinical improvement); lack of self-criticism; increased speed and reduced exactness in motor performance; more extraversion and carelessness; and less regard or interest for other people. The variation of operative procedure had little and only quantitative influence on the test results. The only new and interesting observation was a disturbance of speech discovered by chance during intelligence testing: the abstracting ability and that of generalisation by means of language were found to be impaired, vocabulary was poorer, while the use of words was indiscriminate and lacking in finer differentiation. This seems important because the site of the standard leucotomy is close to Broca's speech centre in the left 3rd frontal convolution. Nobody seems to have noticed this before; the observation was made fortuitously and would have deserved more detailed analysis and fuller description. Altogether, Cattell's statement, quoted by Mrs. Petrie, that in psychology "statistical analysis is a device to bring out relationships and patterns which unaided observation and memory could not perceive" is hardly supported by the work she describes.

It is inevitable that this book should be compared with Partridge's study,[2] published two years ago, of 300 leucotomies done by the same surgeon. He provided a mass of interesting clinical data, but, in rejecting a statistical approach, did not even add up the number of patients in each [illegible] Mrs. Petrie's work is unsatisfying fo: [illegible] that her experiments strike one as too far detached from clinical reality. She gives no account of the condition of the patient at the time of testing, and in only 4 cases offers a short survey of the illness. In their several ways, these two studies thus reflect the continuing lack of an established tradition of clinical research in psychiatry. In this kind of work it is exceptionally difficult, but none the less desirable, to combine a disciplined approach, supported by clear concepts, with a thoroughgoing observation of clinical facts, including test results.

THE HERXHEIMER REACTION

DERMATOLOGISTS know of many drugs only as mischief-makers. It fell to Herxheimer to describe the untoward effects of the drugs invented by his fellow-countryman, Ehrlich. Ironically, the more specifically treponemacidal the preparation, the more likely it is to cause a Herxheimer reaction. There are several objections to the simple explanation that the drug, in killing the parasites, causes the sudden release of breakdown products which then intoxicate the host. Severe reactions sometimes take place where diligent histological search brings to light the presence of no more than a few spirochætes. Furthermore, reactions may follow the administration of therapeutically ineffective quantities of a drug. If, however, a patient is hypersensitive to products of *Treponema pallidum* such reactions are more easily explained.

Anti-histamine drugs given to patients under treatment for syphilis have failed to prevent Herxheimer reactions.[1] This might be due to the release of histamine in the "shock tissues" themselves; certainly, histamine-like substances do not appear in the blood during Herxheimer reactions.[2] Experimentally, infected rabbits treated for three days with 5 mg. A.C.T.H. per kg. body-weight and then given penicillin continue to show the histological changes of the Herxheimer reaction in skin lesions.[3] These changes consist of increased œdema, vascular congestion, and invasion with polymorphs which are later replaced by mononuclear cells. Heyman and his colleagues[3] found it impossible to produce Herxheimer reactions in syphilitic rabbits by injecting spirochætes alive or dead, or after freezing, heating, or mixing the organisms with antisyphilitic drugs. They succeeded, however, in producing a reaction by injecting the animals with pooled immune serum from rabbits with untreated syphilis. Animals infected with *Spirillum minus* and subsequently injected with a serum containing lysing and immobilising antibodies against the organism also had Herxheimer reactions. The solution of this and other immunological problems in syphilis would be greatly helped by culture of the organism and isolation of its antigenic elements.

The histological changes described by Heyman et al. parallel those found by Rich[4] in tuberculous foci after the injection of tuberculoprotein. Specific treatment may aggravate the disease even in the absence of a skin reaction of the delayed type. As Heyman points out, this may be due to lack of adequately antigenic test-solutions rather than to basic differences in the type of disease. He lists reports of Herxheimer reactions in brucellosis, glanders, tularæmia, leprosy, and spirillar and leptospiral infections. To these might be added blastomycosis and paracoccidioidal granuloma, both of which may be made worse by iodides if desensitisation with vaccines is not undertaken. It is curious that such reactions have not proved common in tuberculosis treated by specific chemotherapy, particularly since patients can be sensitive to tuberculin in almost infinitesimal amounts; Goldsmith's[5] patient, for example, showed a severe necrotic reaction to an intracutaneous injection of tuberculin diluted 1 in 20,000,000.

A VITAL EXPERIMENT

THOUGH on a disappointingly small scale, the experiment of general practice from health centres is at last beginning to take shape: the opening of the centre at Knowle West, Bristol,[6] has been closely followed by the ceremony which Mr. Somerville Hastings performed this week on the London County Council housing estate at Woodberry Down. The new centre at Woodberry Down, which is described in a special article on p. 772, is the first realisation in bricks, mortar, and medical care of an ambitious plan; the council has divided its county into 162 health-service areas, each with a population of about 20,000, and it proposes that a health centre be built in each of them. The fulfilment, modification, or abandonment of this plan must depend very largely on the success or failure of Woodberry Down; for the Council's declared policy is to make its health centres "comprehensive"—in other words, to collect, as far as possible, all the health services required by an area into one building—and this policy is now going into practice for the first time.

It is not only the physical properties of a building and the soundness of its functional design that will be put to the test: we can look for new evidence on the equally important questions of how best to organise the health-centre team to bring out the full efficiency and coöperative effort of which it is clearly theoretically capable; and how to rear a new centre in an environment of old-established general practices in such a way as to win over those doctors who are doubtful of its value and disarm the frankly antagonistic. The outcome of Woodberry Down will be important enough to the future of the London medical services, but it will have an even greater national significance, especially if it gives useful answers to these questions; for the comprehensive health centre is probably the kind most likely to give the best service to an urban community and to enable the general practitioner to include a satisfying share of true preventive medicine in his work.

At all events, few have disputed that the experiment is worth trying; and whatever the final judgment on health centres, as a whole or individually, may be those who have been able to inspect the splendid building at Woodberry Down will agree that here are the major ingredients of success. Whether they have been blended in the right proportions, whether there are incompatibilities that have been overlooked, and what further trimmings are desirable, we should know in two or three years' time. When the evidence has accumulated here and elsewhere, it will be possible to assess the experimental centres, not as the wonderful showpieces they now seem, but as the potential working units of the health service.

Sir CHARLES SYMONDS, neurologist to Guy's Hospital, and Mr. H. R. DEW, professor of surgery in the University of Sydney, have been appointed Sir Arthur Sims travelling professors for 1953.

Prof. E. D. ADRIAN, F.R.C.P., P.R.S., and Mr. DENIS BROWNE, F.R.C.S., have been appointed to the reconstituted general advisory council of the British Broadcastng Corporation.

WOODBERRY DOWN

A Comprehensive Health Centre

THE London County Council health centre on the Woodberry Down housing estate at Stoke Newington in North London was opened on Oct. 14 by Mr. Somerville Hastings, F.R.C.S., M.P. Mr. Iain Macleod, Minister of Health, was among those at the ceremony. Next day parts of the school-health, child-welfare, and antenatal units in the centre, and the day nursery next door, came into use. The general medical and dental practitioners' unit will start working later.

As a matter of health-centre policy, the L.C.C. decided that London centres should house as many as possible of the health services needed in a district; and Woodberry Down is the first of the council's "comprehensive" health centres. As Mr. I. J. Hayward, leader of the council, pointed out at a press conference on Oct. 10, the centre represents an experiment, the results of which "will be invaluable in providing the necessary experience to be used in due course in the planning of other health centres."

Built at a cost of about £151,000, the centre contains:

A general medical and dental practitioners' unit.
A school-health unit.
A child-welfare unit.
An antenatal unit.
A remedial-exercise and child-guidance unit.

The day nursery which has been built next to the centre has cost about £21,000.

The centre is a two-storey building on a site of about $1^1/_2$ acres (see fig. 1), with a view over the New River, a reservoir, and an open space. The plans (a part of which are shown in fig. 2) were prepared by Mr. W. J. Durnford, F.R.I.B.A., and Mr. A. E. Miller, F.R.I.B.A., under the direction of the council's architect, Mr. R. H. Matthew, A.R.I.B.A. The former medical officer of health

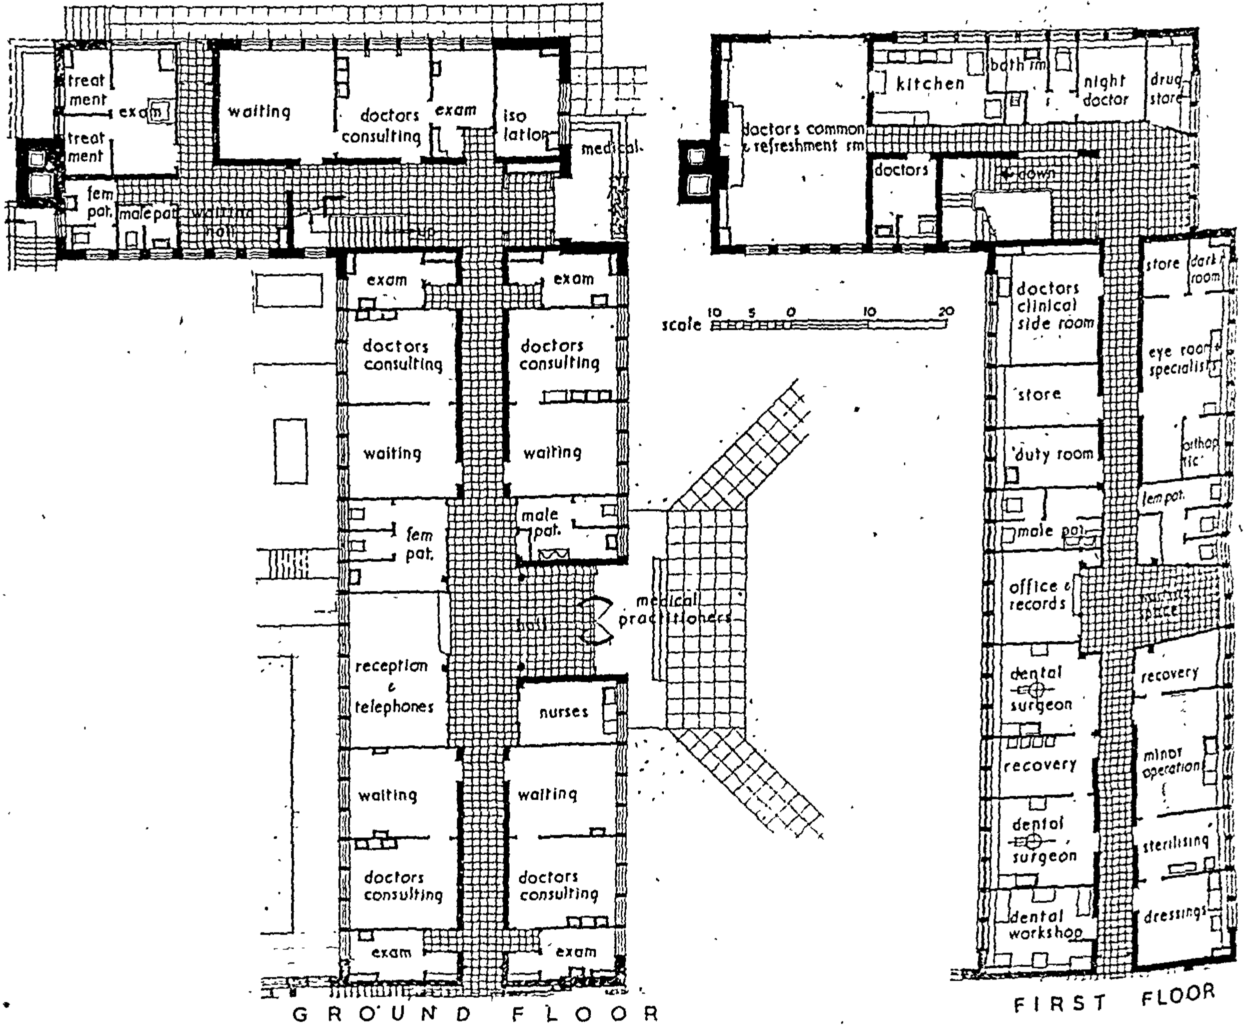

Fig. 2—Part of the plans, including general practitioners' suites on the ground floor.

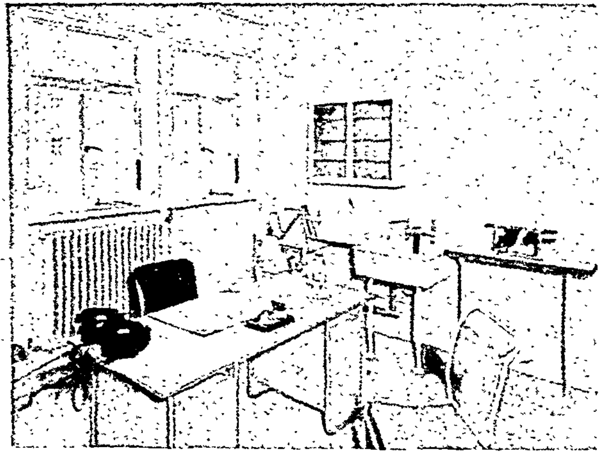

Fig. 3—A general practitioner's consulting-room.

for the county, Sir Allen Daley, F.R.C.P., the present M.O.H., Dr. J. A. Scott, and their colleagues have given detailed advice at every stage.

The design has carefully avoided a single entrance leading to a large waiting-space, common to all the units; instead each unit has its own entrance, and the G.P.s' unit has an entrance and two exits. Though the site was large enough to enable everything to be included on only two floors, it was still hard to decide which of the various units had the strongest claims to ground-floor accommodation. In the end, the ground floor was given to the G.P.s' suites and the adjoining foot clinic, and to the antenatal, child-welfare, and school-health units. This left the upper floor to take the dentists' suites, the minor-operations theatre, the eye-rooms, the doctors' clinical side room, the ultraviolet-light and remedial-exercises rooms, the child-guidance unit, and staff refreshment-rooms and common-rooms. Work on the building began in March, 1949, and it was finished last month.

For planning purposes the L.C.C. has divided the county into 162 health-service areas, each with a population of about 20,000; the ultimate aim is to provide a health centre in each area. But the use of the new centre will not be restricted to those in the Woodberry Down area, and the centre may well serve as many as 24,000 until other centres are built in adjoining areas.

PROVISIONS FOR GENERAL PRACTICE

Six doctors will run their practices from the centre. For some time the L.C.C., the London Executive Council, and the Local Medical Committee for London have been discussing the arrangements under which G.P.s should work in the centre. There are at present about sixty doctors in practice within a mile of the centre, and it is expected that the executive council will nominate the six from among them. Clearly the terms of the contracts that will be made have required very careful consideration, and the legal advisers of the Ministry of Health and the British Medical Association have been consulted. The precise terms have not yet been announced, but it is known that each practitioner will be asked to pay a certain sum in return for the facilities which he will use in the centre. This sum will be based on an estimate of what it costs to provide an adequate surgery, waiting-room, and so on in private premises in the district; the figure of £350 a year has been mentioned as a possibility. It is hoped that the doctors will be chosen in time to allow them to start practice from the centre early next year.

The layout of five of the doctors' suites is shown in fig. 2.

The central entrance opens into a small waiting-hall with a record office and inquiry desk, and corridors lead from the hall to the doctors' rooms. Each suite consists of a waiting-room (14 ft. by 12 ft.), a consulting-room (the same size) (see fig. 3), and an examination-room (9 ft. by 8 ft.). There are washbasins in the consulting and examination rooms. A door leads directly from the consulting-room into the main corridor, so that patients need not return to the waiting-room.

The unit includes an isolation-room near one exit where infectious cases can be dealt with and, if necessary, await removal by ambulance. The foot clinic is also in this part of the building (at the end of the wing shown in fig. 2), but it has its own entrance.

The other rooms which will be used regularly by the G.P.s are on the first floor, immediately above the consulting-rooms, and are reached by two wide staircases. There is a minor-operations theatre, with a sterilisation room, a room for doing wound dressings, and a recovery room.

Another set of rooms has been designed for ophthalmic work; they include a darkroom and an orthoptic room. The main eye-room is intended for the use of other consultants who may visit the centre.

An important feature is the clinical side room where doctors can themselves carry out the simpler investigations. A small medical store has been provided in which materials to be used on the premises will be kept; drugs will not be dispensed from the centre, and patients will take their prescriptions to the chemist in the usual way. A part-time pharmacist will be employed in the medical store.

This part of the building also includes a bedroom and bathroom for the doctor who is on duty for night calls; and there is a common-room for the medical and dental staff, with a small service kitchen attached.

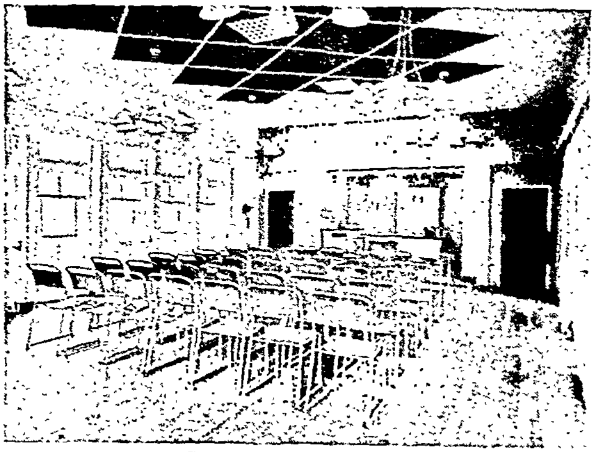

Fig. 4—The lecture hall.

THE DENTAL SURGERIES

The two dental surgeries shown in fig. 2 will deal with dental patients generally; two other surgeries nearby will be used exclusively by the priority classes (expectant and nursing mothers and children). Recovery-rooms and dental workshops are attached. A dental X-ray unit has been installed in a room large enough to take equipment of higher power, should it be decided later to do more radiological work in the centre.

Two dental practitioners, to be selected and engaged by the London Executive Council, and two dental officers of the maternity, child-welfare, and school-health services will work in the centre. Two surgeries may seem inadequate for a population of 20,000, but the unit is not intended to replace all dental surgeries in the area.

THE COUNTY-COUNCIL SERVICES

School-health Unit

A separate entrance from a quiet side road leads to a waiting-hall, a room for dealing with minor ailments, a doctors' consulting-room, a nurses' room, and a record office. On the floor above are the two dental surgeries for priority patients, and another eye-room, with darkroom and orthoptic room attached.

Antenatal Unit

Here there are interviewing rooms for the use of health visitors and midwives, a room with undressing-cubicles and urine-testing facilities, where patients will be seen by the midwives, and a doctors' consulting-room.

Child-welfare Unit

This unit also opens off the quiet side road. There is a large room for toddlers near the door (which looks out on to a playground) a pram store, and a room where welfare foods will be on sale. A test-feed room and a weighing-room are included in the unit.

Child-guidance Unit

There are consulting-rooms for the psychiatrist, the educational psychologist, and the psychiatric social worker; and a playroom for the children.

Other Facilities

Ultraviolet-light treatment will be provided on the first floor, mainly for patients from the antenatal and child-welfare units; and the remedial-exercises room, primarily intended for schoolchildren, will also be shared by the various units. A lecture hall (36 ft. by 22 ft.) on the ground floor is equipped for showing films, and also contains a demonstration kitchen (see fig. 4).

STAFF AND MAINTENANCE COSTS

Apart from the six general and two dental practitioners, and certain specialists to be provided by the North-East Metropolitan Regional Hospital Board, the L.C.C. will staff the centre. A provisional indication of the staff required is as follows:

G.P. Unit	
General medical practitioners	6
Dental practitioners	2
Pharmacist (part-time)	1
Clinic nurses	2
M[illegible] Child-welfare and School-health Services	
[illegible]	1
[illegible]	1
[illegible]	2
Centre superintendent	1
Health visitors	4
Midwife	1
Psychiatrist (part-time)	1
Educational psychologist	1
Psychiatric social workers	2
Physiotherapist (part-time)	1
Chiropodist	1
All Services	
Senior dental technician	1
Dental technicians	2
Dental attendants	4
Centre administrative officer	1
General clerical officers	6
Telephone operators	2
Caretaker	1
Cleaners	7
Stoker-porters	3

It is estimated that the cost of running the centre in its first full year of work will be about £21,000 for the local-health-authority services and about £12,700 for the general medical and dental services. But some of the expenditure on the council's services will be offset by the transfer to the centre of staff and clinics from premises that are being closed.

OPENINGS FOR GENERAL PRACTITIONERS

THE Medical Practices Committee has now classified the practice areas in England and Wales into three categories instead of four, in accordance with the recommendations of the Working Party on the Distribution of Remuneration among General Practitioners. The new classification comes into force at once for the purpose of admission to the medical lists of executive councils. The list will be revised from time to time, and a doctor who is proposing to enter practice should apply for up-to-date information from the local executive council before taking steps to secure surgery and waiting-room accommodation. The three categories are as follows.

Designated Areas

Admission to the medical list in any of these areas will be automatic. In urban areas the designation does not necessarily apply to any part where the population density is lower than in the area generally—e.g., the rural fringe of many urban areas. In rural areas the designation applies to the centres of population only. The position in designated areas is fluid and may change rapidly with the introduction of new doctors. The names of areas where the position is finely balanced and the admission of one or two doctors only may result in reclassification are marked with an asterisk on the committee's list. Under the Working Party's report an initial practice allowance may be claimed only for new practices in a designated area. Details of the scheme for the payment of these allowances are to be published later.

Doubtful or Intermediate Areas

Admission to the list to practise in these areas will be decided in the light of circumstances at the time of application. Automatic acceptance cannot be assumed. In the areas where the position may be changing at the time an application is made—perhaps because of housing development—the classification may, after the comments of the executive council and local medical committee have been considered, be amended to designated. The designation will apply only to the practice district for which application has been made. Other considerations may lead the committee to decide that the number of doctors already practising in the area is adequate and that the application be refused.

Restricted Areas

These are areas in which the committee has decided that the number of doctors practising is adequate. Normally applications to start new practices will not be granted, but in an existing practice regard will be had to all the circumstances of the case.

Further particulars may be had from the Medical Practices Committee, 3, Deans Yard, Westminster, London, S.W.1, but details of individual areas should be obtained from the local executive council.

Occasional Survey

FIBRILLOGENESIS

THE effects of adrenal corticosteroids on the collagen diseases have not only stimulated conjecture about the causes and relationships of these conditions, but have also led to a renewed interest in the structure and physiology of normal connective tissue. Much of the recent work on this complex, labile, and largely extracellular tissue centres around the nature and origin of its fibrillar elements, and the relation they bear to the mucopolysaccharides of the ground substance.

The electron microscope has been a great help in these investigations. Electron micrographs show that collagen fibres, as identified histologically, are composed of bundles of smaller fibrils embedded in cementing substance. As Gross [1] points out, histological alterations in collagen fibres cannot therefore be ascribed to collagen itself, unless the abnormality can be localised in its component fibrils. The interfibrillary ground substance has an organised molecular structure,[2] but it does not seem to be closely adherent to the fibrils, for it can be washed away from teased tissue with water. Electron micrographs also show that the washed collagen fibrils vary considerably in width (700–1400 A°), but they are regularly cross-banded,[3] [4] the average distance between bands being 640 A°.[5] There is also a characteristic

---

complex of intraperiodic sub-banding, which serves as a "finger-print" for the identification of normal collagen, independent of age and (probably) of vertebrate species.[5]

This precise and complicated picture of the collagen fibril at once poses the question of fibrillogenesis. Is this highly organised structure condensed from the intercellular substance, or does it originate in the connective-tissue cells themselves? Earlier workers favoured the extracellular concept, and some later experiments have supported this view.[6] It was shown in 1927 by Nageotte [7] that rat-tail tendon was partially soluble in dilute acid, and that when salt was added to the solution fibrous collagen was precipitated. This reconstitution phenomenon has been closely investigated in attempts to test the extracellular theory of fibrillogenesis. The X-ray diffraction pattern [8] and the appearances under the electron micrograph [4] of such reconstituted collagen confirm that it retains its characteristic striations. In-vitro studies by Vanamee and Porter,[9] who used the electron microscope to follow the stages of reconstitution of fibrils from acid solutions of collagen, showed that salt solutions and an increased pH (5·3) were equally effective in precipitating collagen-type fibrils. When a film of dissolved collagen was exposed to these conditions for short controlled periods, they found that, at an early stage in fibril formation, needle-like crystals of collagen were produced, which showed periodic banding at intervals of about 210 A°. Fibrils were found in which regular stressing of two out of three such bands resulted in the typical 640 A° macro-period of normal collagen. They concluded, as others had done, that what they were observing was the aggregation of the smallest units that can be resolved by the electron microscope; and they inferred that in acetic-acid solutions, at any rate, these units were still fibrous, and that they were probably basic collagen units, or molecules, 640 A° long.

The experiments of Gross et al.[10] with acid extracts of carp swim-bladder showed that collagen fibrils may be effectively reconstituted by a low concentration (0·001%) of serum-acid-glycoprotein; but this effect was nonspecific for it was also produced by a variety of other substances, such as thrombin, papain, *Clostridium histolyticum* proteinase, and adrenocorticotropic hormone. They showed, too, that mucopolysaccharides (chondroitin-sulphate hyaluronate and heparin) precipitated salt-free collagen solutions, but that the fibres formed showed periodic banding with much longer spacing (2100 A°) than normal collagen. This and other work on reconstituted collagen, although of great interest in clarifying its structure and nature, does not give conclusive evidence of its source in connective tissue. Porter [11] has lately studied the formation of fibrils in tissue cultures of chick-embryo skin, fixed in osmium tetroxide, after different periods of growth. His observations with the electron microscope are convincing proof that collagen fibrils are actually formed at the surface of fibroblasts, and suggest that they originate in the ectoplasmic zone beneath the cell-membrane.

Meyer's theory of fibrillogenesis [12] proposes that collagen is precipitated on to polysaccharide fibrils, whose regularly spaced acidic groups form a template on which the fibril is built. Morrione [13] points out that although most observers believe that fibroblasts elaborate the ground-substance polysaccharides, definite proof of this is lacking. His experiments show that very low concentrations of heparin (1 in 80,000) can precipitate typically striated fibrils from collagen solutions, and he suggests that, in vivo, the heparin produced by mast cells plays a part in the formation of collagen. Although mast cells may be present in increased numbers in chronically inflamed connective tissue, there seems little reason at present to conclude that heparin is of major importance in fibrillogenesis. It has been shown [10] that collagen fibrils themselves possess a carbohydrate-containing fraction which is still detectable in reconstituted collagen; and an interesting report from Leeds University [14] says that polysaccharide and sulphuric acid are intimately associated with the protein of elastic tissue, another fibrillar element of connective tissue.

The functional relationships of the fibroblast with both the fibres and the ground substance of connective tissue may be of great importance in the pathogenesis of the collagen diseases. Modern research techniques are quickly expanding our knowledge of the processes involved.

Medical Congresses

NUTRITION RESEARCH

THE Second International Congress of Nutrition was held in Basle on Oct. 1–4. The First International Congress, held in London in 1946, owed its inception to the British Nutrition Society, and was made financially possible by the generous aid given by the British Council. The London congress afforded to nutritional scientists from many lands—13 different countries were represented—the first opportunity of getting together again after the war, and discussing their wartime experiences and problems: most of them had been under enemy occupation or had suffered from food shortages. It was at that Congress, too, that an International Union of Nutritional Sciences took shape, the aim of which was to bring together the nutrition societies and scientists of different lands. A committee was formed with representatives from 14 countries, Prof. E. J. Bigwood, of Brussels, being elected the chairman and Dr. L. J. Harris, of Cambridge, the secretary-general. Subsequently, various business meetings and small-scale conferences were held in London, Copenhagen, and New York; and the Union became officially affiliated to the appropriate United Nations organisations.

This second full-scale congress at Basle, which was held in the buildings of the new university there, owed its success largely to the efforts of the local organising committee, under the enthusiastic directorship of Prof. F. Verzár. Some 150 registered members from 18 countries heard about twenty-five papers or formal contributions to the discussions. The social occasions, which always form so important a feature of such international meetings, did everything possible to confirm the high reputation which Switzerland holds for hospitality and generosity.

National Nutrition Policies and Problems

The topics discussed at the scientific sessions covered a wide range. Adequate nutrition depends ultimately on an effective agricultural system; and at the first session Prof. A. I. VIRTANEN, of the Biochemical Institute, Helsinki, stressed how pressing is the need for agricultural production to be stepped up by the application of modern scientific principles. It was essential, however, that full consideration should always be given to important regional differences and requirements.

He declared himself an optimist in the race between increasing populations and a developing agriculture. J. Trémolières, chief of the nutrition section of the Institute of Hygiene, Paris, emphasised how much the dietary patterns, and the expenditure on food, varied from country to country and from one part of a country to another, and also how these patterns might change with the passage of years. The increased consumption of milk, and the growing desire for pasteurised milk in France is beginning to follow the trend with which we have already become familiar in the United Kingdom.

Later, D. P. Cuthbertson, director of the Rowett Research Institute, Aberdeen, brought the congress back to underlying scientific theory by recalling that it is the physiology of ruminant digestion—detailed knowledge of which is still in a relatively rudimentary stage—upon which depend all our meat and milk production. Prof. H. Kraut, of the Institut für Arbeitsphysiologie, Dortmund, raised the question of the influence of diet on muscular stamina. He maintained that he had found stamina to be subnormal in groups of German workers or students when their daily dietary intake of protein had fallen below 1 g. per kg. of body-weight.

The practical significance of vitamins in relation to national health policy was the theme of a paper by Leslie Harris, director of the Dunn Nutritional Laboratory, Cambridge. He compared the official measures taken in Britain and elsewhere to ensure an adequate vitamin intake, such as the vitaminisation of margarine, the longer extraction-rate of wheat flour, and the provision of vitamin concentrates for mothers and babies. He also reviewed critically the various claims advanced for vitamin therapy, some of which he regarded as legitimate, and others to be attributed to "sales pressure" or to the overenthusiasm of experts.

Interrelations of Vitamins, Minerals, and Hormones

The remarkable variety of abnormalities which can result in animals from a deficiency of vitamin E were enumerated by Prof. H. Dam, of the Polytechnic Institute, Copenhagen. Cod-liver oil, as he mentioned, can oppose the action of vitamin E; and, on the other side, administration of the dyestuff, methylene-blue, can replace the vitamin. After a full discussion, in which T. Moore, of the Dunn Nutritional Laboratory, Cambridge, S. Markees, of Messrs. Hoffmann-La Roche, Basle, and I. Leitch, of the Imperial Bureau of Animal Nutrition, Aberdeen, participated, the eventual conclusion seemed to emerge that the cod-liver oil probably exerted its anti-vitamin-E effect by promoting the oxidation (and hence the destruction) of the vitamin, whereas the methylene-blue, in the contrary direction, acted as an antoxidant.

Further reviews of the interactions between vitamins and vitamin antagonists, or anti-vitamins, were contributed by Prof. J. Kühnau, of theBioch emical Institute, Hamburg, and by J. C. Somogyi of Berne.

In Switzerland, as in many other countries, dental caries is prevalent; but speakers from different regions—for example V. Demole, of Lausanne, Prof. T. Gordonoff, of Berne, and Prof. A. J. Held, of Geneva—expressed rather divergent views about the desirability of adding traces of fluoride to drinking-water or to table salt. One speaker held that added fluoride might adversely affect the iodine balance—and this might be of practical consequence in localities where endemic goitre had been prevalent. A paper by Prof. H. D. Cremer, of the biochemical institute of Mainz University, went further to stress how much still remained unknown *about human requirements for the various* ineral elements.

S. J. Folley, of the National Institute for Research in Dairying, Shinfield, revealed new horizons in describing how the artificial application of hormones to farm animals might be used, for example, to increase the production of cow's milk or even of poultry meat. A hope was expressed by some that, for the present, these new developments might be regarded as no more than a valuable tool in research—and not as a practical proposition in current veterinary or clinical practice.

The effect of cortisone in influencing the utilisation of food was discussed by S. G. Greenberg, of the University of California, Los Angeles.

Fat and Protein in Nutrition

Contributions to our knowledge of fat and protein in nutrition were made by several speakers. Prof. E. J. Bigwood, of the laboratory of physiological chemistry and nutrition of the University of Brussels, described *developments in chromatographic technique*, by which he could identify the constituent amino-acids in intact *protein-containing foodstuffs.*

Prof. K. Bernhard, of the biochemical institute at the University of Basle, found that phytol, a component of chlorophyll, had a physiological rôle similar to that of choline, in preventing an undue accumulation of fat in the liver.

The surprising claim was made by A. B. L. Bezsák, of the department of physiology, Birmingham, that rats receiving diets low in fat and in vitamin B_1, and therefore failing to thrive, had done better when they were forced to undergo strenuous physical exercise.

Food Manipulation

Prof. Karl Thomas, now working at the Max-Planck Institute, Göttingen, referred to the investigations which have been proceeding in Germany to explore the possibility of converting paraffin oils or waxes, and various waste materials, into fats, which could then be used for foods. He discussed the metabolism of abnormal fats, as influenced by the presence in the molecule of branched chains, and of methyl groups. A. Schürch, of MacDonald College, Montreal, and Zürich, warned the meeting that linseed oil, which had been used in America for culinary purposes, might when heated give rise to undesirable toxic products. Prof. K. Lang, of the biochemical institute of the University of Mainz, in turn described the changes which might be undergone by protein as a result of heat, or of conservation processes.

Such contributions as the foregoing set the background for Prof. O. Högl, of the Public Health Office, Berne, and Prof. E. Abramson, of the National Institute of Public Health, Sweden, both of whom spoke of the need for more effective control in checking *the practice* of adding chemicals or "improvers" or other artificial colouring, flavouring, or preserving agents to foodstuffs. Professor Abramson argued persuasively for the setting up of a central laboratory for examining these problems, and for exchanging information, on an international level.

Finally, W. R. Aykroyd, director of the Nutrition Division of F.A.O., spoke of the current activities, and problems besetting that organisation. He did not hide some of its past disappointments and failures, but neither was he without hope for the future.

* * *

Before leaving Basle, the committee gratefully accepted an invitation to hold the next congress in 1954 in Amsterdam—a very happy choice in view of the pioneer work in nutritional research of many Dutch investigators, including Eijkman, Pekelharing, and Jansen.

In England Now

A Running Commentary by Peripatetic Correspondents

WHAT a convenient thing for authors and scenario writers hysterical conversion has turned out to be. Other aspects of character which go with this disorder can be ignored in favour of a nice paralysis at once romantic and emotionally loaded, developed as an isolated symptom and capable of perfect cure. In *Limelight* Mr. Chaplin endows the prettiest of ballerinas with this convenient disability, and capably restores her by a combination of Freudian catharsis—as early as 1914, too!—and a severity out-Gordoning Holmes. Both methods are successful on their appropriate occasions and the lady dances devoted attendance on him till he pegs out, more or less in the big drum. But he has been clever about releasing her from the transference, and clearly she is going to grow up and be as happy as most. There is nothing new in this particular plot, but Mr. Chaplin cheers it up enormously. What's more, he gives us a first-class psychological study of an ageing comedian, with his sense of failure, his outstanding gifts, his moodiness, generosity, vanity, and courage. We all know well enough that the ability to be funny must depend on self-confidence—everything falls flat when the comedian doubts himself—and that the flimsiest material can explode into wit when it is backed by craftsmanship and belief. But he shows us the mechanism of this common theatrical experience most beautifully in the final uproarious scene with Buster Keaton, a piano, and a violin, and there is some glorious nonsense when one of Charlie's legs is attacked with bouts of shrinkage. It takes all his contemporaries back to the laughter of their youth just as it is meant to do.

* * *

The ambitious student has always begrudged the hours he must spend in idle sleep. But the results of a recent American experiment—highly reminiscent of Aldous Huxley's *Brave New World*—suggest that he may be able to increase his store of knowledge even while taking the necessary amount of recuperative slumber. A class of American students, who were learning Chinese, was divided into four groups. The first, while sound asleep between the hours of 2 A.M. and 3.30 A.M., had a record played to them of a list of unfamiliar Chinese words followed by the English equivalents. It was found next morning that they took considerably less time to learn this list than a second control group who had been allowed to slumber unserenaded in this polyglot fashion. To the third group Strauss waltzes were played in the small hours, and this had no effect one way or the other on their learning-rate. But the fourth batch, to whom the same list of Chinese words was played, but with inaccurate English equivalents, found it took them a good deal longer next day to learn the correct meanings. This investigation may comfort lecturers who are apt to feel disheartened by the postprandial somnolence of their audience. Some, at any rate, of their precious flow of information may be soaking into the stony ground before the rostrum.

* * *

"There you are Mr. Thurkington. Now go home, take things easy, and come in again tonight for another injection. If it isn't beginning to clear up by tomorrow, we'll have to take sterner measures, but I hope this'll do the trick."

"Darling, I think I must have something coming up on my arm, a boil or something. No, it isn't very much, just an area of redness and tenderness, but it might develop. Probably bruised myself going through Casualty doors this morning. No, I shan't be home late—I'll just have a game of squash with *Bill*—I promised I would—so, it'll probably be about eight o'clock. See you later, darling."

"Yes, dear, it does seem to be a bit worse this morning. Perhaps I'll pop down to Casualty and get Sister to give me a shot of penicillin later on. No, not really painful, thanks. I'll see how it goes. Yes, I remember Mrs. Thingummy and the time you had an abscess *on* your cheek. No, nothing much today, I'll be home early—just a swim before I come down."

"No, I haven't been to Casualty yet—I'm such a coward about these injection things—always think the Sister has a grudge against me or something. Yes, I promise I'll go if it gets any worse."

"Sorry, old man, I don't think I'd better play tonight—I seem to have a carbuncle developing on my arm. No, I haven't taken medical advice yet—I'm scared stiff of doctors really. Yes, I know what advice I'd give a patient but it doesn't seem to be very bad, it may clear itself. Still, perhaps I'd better not play squash tonight. Sorry."

"No, darling, I haven't had time to go to Casualty yet. Don't nag, my sweet."

"Sister, do you think I could have a brief course of penicillin and so on? I seem to have a boil of sorts on my arm. Had it a couple of days now, as a matter of fact. Yes, Sister. All right, Sister—ouch!"

"Yes, darling, I have been to Casualty, and I'm going again tonight. It's a bit more painful, but I'm too busy to do much about it."

"Yes, dear, I'm having a course of penicillin—of course, we don't know that it's a penicillin-sensitive bug I've got, but still. Yes, they generally take cultures, but I didn't bother with that. Yes, there do seem to be some red lines up my arm, and it's a bit tender in the armpit."

"Fortescue, do you think you could possibly have a look at my arm? It seems to be a trifle worse today. What, have it incised? Is it absolutely necessary, old man? I mean, I'm such a coward over these things. Oh well, if you promise to put me to sleep nicely."

"It was very sweet of you to turn up so promptly, my love—awful coming round from an anæsthetic—can't think how patients stand up to it."

"Yes, thank you, healing nicely—can't think why I made such a fuss really. Well, say in about a week—bet you five bob I beat you hollow."

"Well, Mr. Thurkington, that seems to have done very well. These things generally heal beautifully if you only take them in time."

* * *

On the road to the south, and but a few miles from Stonehenge, is a large military establishment in a country estate which, without disguise, proclaims itself a Joint Concealment Centre. The most unkind guess from our party was that it contained a depot of the Ministry of Food.

* * *

Perhaps it was as well that I was in the manic phase when the examiners in Anatomy failed me. Instead of troubling the river police, I spent quite a useful long weekend. Not content with distempering one room, I redecorated the flat and was only just restrained from doing the neighbour's. In case there should be any physical energy left to vent on the examiners, and thus add trial by jury to my misfortunes, I then resurrected the car from a trans-Sahara state to the most indecent showroom condition. (I now spend sleepless nights listening for sounds of someone attempting to restore her to the showroom, but at last my friends believe me when I try to convince them that I own an A 40.) My literary energy I diverted from the President of the College to the Editor of THE LANCET. A spate of contributions will be loosed on the unsuspecting man at seemly intervals (his non-committal acknowledgments jar the Ego so much less than the rejection slips which are said to paper the way to literary adequacy). I then took out a dignified sheet of paper and wrote a letter to the Editor of a rival weekly, gently chiding a great one who had had the temerity to allow his article to be published the day the results were out. At this rate I should be able to master Anatomy in the weekend before the next exam.

On second thoughts, I will have my chest X-rayed. One of my other diseases would be preferable to a depression centred over the next ten guineas' worth.

* * *

News from School.—Yesterday we had a lesson in Biology on Harvey's experiment. We had to tie a cloth round our arms and then watch the veins appearing. When they did we drew them in with blue chalk. Then we found the arteries and did them in red. That with a lot more went to prove that blood circulated, which was pretty obvious anyway.

Letters to the Editor

THROMBOPHLEBITIS FOLLOWING INTRAVENOUS INFUSIONS

SIR,—The paper by Mr. Bolton Carter and his colleagues (Oct. 4) on this topic has been of particular interest to us as we have been conducting an investigation along rather similar lines.

During 1951, thrombophlebitis after intravenous infusions was very common in this hospital and was often a cause for more complaint than the operation which occasioned the infusion. Despite the severity of some of the reactions suppuration never ensued, and this suggested that bacterial infection was not the cause. Good splintage and use of 'Polythene' cannulæ did not reduce the incidence of thrombophlebitis in a short series: it therefore seemed unlikely that damage to the intima by cannula or needle was the cause of the reaction. We were left with the possibility of a chemical irritant introduced in the infusion fluid, and believed that we had discovered this when we found that the 4% dextrose with 0·18% saline solution in use had a pH of 3·6 to 4·0. A solution of this degree of acidity seemed likely to irritate a vein with which it was in contact over a period of some hours. In view of the results obtained by Bryan and Grainger[1] it was decided to add a buffer to the infusion fluid immediately before administration. After trials it was found that the addition of 2·5 ml. of a 5% solution of disodium hydrogen phosphate in distilled water consistently raised the pH of the dextrose-saline to 7·0. For convenience the dose of buffer was sterilised in 5 ml. insulin bottles, one of which was strapped to each bottle of dextrose-saline. The buffer was tipped into the dextrose-saline immediately before use.

From January to June, 1952, trials were conducted using this buffer solution, and a control solution which was simply sterile water for injection. The latter was also packed in insulin bottles strapped to the dextrose-saline bottles, and both buffer and control were labelled with key letters so that neither the nursing staff nor the investigator who recorded the state of the patient's arm knew whether plain or buffered dextrose-saline had been given. Precautions were taken, however, to ensure that each infusion once started was continued with the same buffered or control solution, and buffers and controls were used concurrently throughout the period of investigation. The dose of buffer was easily added, and as it was secured around the neck of the bottle it could not be forgotten. All drips in this investigation ran for more than 12 hours, most for more than 24 hours, and all patients received more than 1500 ml. of dextrose-saline. Results were as follows:

	Buffer series	*Control series*
Thrombophlebitis	5	19
Thrombosis..	6	5
No reaction..	13	5
	24	29

These results appeared to be significant, and it was decided to make a trial of buffered solutions only. In view of the report of Handfield-Jones and Lewis,[2] it was felt desirable to control the tubing used in the giving sets. New sets were therefore obtained fitted with one particular brand of rubber tubing only. The tubing used in previous sets had been of various makes. Since the end of June, patients receiving dextrose-saline infusions have been given only buffered solutions and only the new sets used. It soon became apparent that the incidence of thrombophlebitis was again very high. In a series of 28 consecutive patients, 18 had thrombophlebitis and most of these suffered very considerable discomfort. Many other cases were seen, including some patients who had blood or Hartmann's solution only. It now appears that the tubing used in these new sets was of the same make as that found by Handfield-Jones and Lewis to produce a high incidence of thrombophlebitis. Clearly, any possible benefit from using buffered solutions was being masked by the effects of a more vigorous irritant, probably derived from the tubing.

We record these experiences because they seem to have an important bearing on the results obtained by Mr. Bolton Carter and his associates. Glucose solutions are generally recognised as liable to produce thrombosis. There must be a reason for this, and an acceptable explanation would be their unusual degree of acidity, correction of which might be expected to reduce the incidence of thrombotic complications. Our first series lent support to this theory; though admittedly small it was carefully controlled, and it seems unlikely that irritant types of tubing were used almost exclusively in giving non-buffered solutions. Further, most of the drips in this series had the more stringent test of running for 24 hours: we feel it should be our aim to secure conditions in which intravenous drips will run for days, if need be, and not only for 8 hours.

With these results in mind, we suggest that the negative results in the trial of buffered solutions by Bolton Carter and his colleagues may be explained in two ways. First, the rubber tubing. The type used in their trial is not mentioned, and possibly if it was not controlled there may have been a change of make during the time of the trial and more irritant brands may have been used during the tests of the buffered solutions. Your annotation (Oct. 4, p. 672) is a startling disclosure of the many toxic substances which rubber may contain. Secondly, the buffering. The "deep brown" solution had a pH of 5·6; although this reaction is less acid than some glucose solutions, it is still distinctly acid.

It is our conclusion that the effects of buffering solutions of glucose can easily be masked by other factors producing thrombophlebitis. In a complete trial of buffered solutions these other factors must be controlled, and only then can we be reasonably certain whether the correction of the acidity of glucose solutions affects the incidence of thrombophlebitis.

BUTAZOLIDINE

SIR,—During the past three months I have treated 15 cases of rheumatoid arthritis which had been present for at least three years, and in some cases for as long as fifteen years.

All 15 patients were admitted to hospital and a diagnosis of rheumatoid arthritis established as accurately as possible by evaluation of the history, clinical signs, X-ray examination of the affected joints, and the erythrocyte-sedimentation rate. All had been treated previously with one or more courses of gold during the past two and a half years, the majority under my own supervision, without any marked influence on the course of the disease.

After about a week in hospital I gave 800 g. of butazolidine by mouth daily. Without exception, after the first dose the patients noticed improvement in their joint conditions. The joint pain and swelling began to disappear after the first dose; the joints which had been affected the longest responded the earliest. Within a day the pain had subsided, and within three days the maximum improvement in the swelling of the joints was achieved.

I have particularly noticed that the small joints of the hands and feet responded better than the larger joints when these were also affected. After a day's dosage, 3 of the patients, hitherto in severe pain and with much reduced activity, had so improved that they demanded to go home. I have continued treatment with this drug for fourteen days. In all cases within a week of stopping the drug the condition

---

1. Bryan, G., Grainger, H. S. *J. Pharm., Lond.* 1950, 2, 471.
2. Handfield-Jones, R. P. C., Lewis, H. B. M. *Lancet*, 1952, i, 585.

deteriorated and became as it was before giving the butazolidine.

I have not experienced any of the serious side-effects, such as the generalised œdema or severe maculopapular eruptions described by Dr. Loxton and his colleagues (Oct. 4). Only 1 of my patients suffered from a mild maculopapular type of skin rash, which affected the face and upper part of the body and disappeared within three days of stopping the treatment. My experience, therefore, is more in keeping with that of Dr. Peebles Brown and Dr. Currie (Oct. 4) who reported that of 280 patients only 3 had developed skin rashes.

I asked each patient the same question: "Have you ever had any tablets or other treatment for your rheumatoid arthritis which has been as effective as these tablets?" and in each case the answer was "No."

I am convinced that here we have an effective new weapon in our fight against the disabling symptoms of rheumatoid arthritis.

Dudley Road Hospital,
Birmingham.
R. O. GILLHESPY.

SIR,—I have been following the correspondence about this drug with considerable interest. A recent three months' trip to the United States, where, of course, it is being used extensively, convinced me that it was valuable though it had disadvantages. As far as I can see, most of the complications mentioned by your correspondents have also been noted in America, and evidence was accumulating there that gastric and duodenal ulceration was commoner in cases treated with butazolidine than in untreated cases. I heard of no fatalities.

Personally, since I came home I have not felt inclined to give butazolidine to outpatients, and so far I have confined its use to patients in my wards. Its greatest value—and this, I think, has not been mentioned by any of your correspondents—is that, given in conjunction with cortisone, it allows the dosage of the latter to be reduced to such an extent that side-effects are practically eliminated.

Butazolidine is, without doubt, useful in the treatment of certain of the "rheumatic" diseases but should be given only under close supervision. Because of certain undesirable side-effects, we should not condemn it entirely but treat it with the respect given to other useful drugs with equally unpleasant side-effects.

Southern Hospital,
Dartford, Kent.
J. C. HOGARTH.

SKIN BANKS

SIR,—The strict conclusion to be drawn from the investigation by Dr. I. J. Good (Aug. 9) is that if there are n independent skin antigens then the probability P that the skin of a donor chosen at random will survive permanently when grafted to a recipient also chosen at random is such that $1 \geqslant P \geqslant (3/4)^n$.

This is an interesting result which might be used to estimate a lower limit for n if we had enough reliable observations of the behaviour of skin homografts in man to make a reasonable guess at the value of P. Unfortunately, at present, this is not so.

Good attempts to reverse this procedure and suggests that it is possible "from what is known of skin grafting in rabbits and the transplantation of tumours in mice" to make a "fair guess" at n and so estimate P. This claim is, however, open to grave objection, as the following considerations will show:

1. As far as I am aware, no instance of permanent survival of a skin homograft in the rabbit has ever been reported (excluding the special case where members of a highly inbred strain are used). The most one can do, therefore, is to estimate a lower limit for the value of n in this species.

2. Even if we knew the value of n for the rabbit it would be dangerous to assume the same value for man.

3. Homotransplants of tumours are much more successful than homotransplants of normal tissues, one likely reason being, as Gorer has shown, that tumours are in general antigenically simpler than normal tissues. How then can one deduce the behaviour of transplants of skin from observations on tumours?

In this connection it is worth mentioning that it seems likely that the number of antigens differs even for different normal tissues. In my own experiments, for example, there have been several instances of very long survival of subfascial homotransplants of thyroid in guineapigs from a mixed population without special treatment. Transplants of skin in the same species have, on the other hand, been uniformly unsuccessful.

In conclusion it must be emphasised that a small change in the value assigned to n makes a vast difference to the lower limit we obtain for P. Thus it will be clear from the following figures:

n	$(3/4)^{-n}$
20	316
21	422
25	1334
30	5623
50	1,778,000
100	$3{\cdot}16 \times 10^{12}$

The optimist will be happy to choose n = 20 corresponding to $P \geqslant \frac{1}{316}$; if, however n = 30 all we can say is $P \geqslant \frac{1}{5600}$. If n = 100 our only consolation is the knowledge that $P \geqslant \frac{1}{3 \text{ million million}}$. It would be unreasonable to put $P = \frac{1}{3 \text{ million million}}$ (corresponding to the "unduly pessimistic" assumption that all the πs in Good's terminology are zero) but even so the outlook would seem to be pretty bleak.

Speculation of this kind is, however, fruitless, and the important thing is to get on with the job of making accurate observations of the behaviour of homotransplants *in man*.

PHLEBOTHROMBOSIS AND NERVOUS STRESS

SIR,—Mr. Stoker (Oct. 11) has done a considerable service in pointing out that recumbency in the home is less likely to produce phlebothrombosis than recumbency in hospital. His hypothesis that the difference can be explained by the mental stresses inseparable from hospital treatment may be correct, and (if he will forgive the pleasantry) has long been accepted by thriller-writers, whose characters frequently suffer from curdling of the blood when startled by some menacing sound or sight.

However, one cannot help feeling a little sceptical at the ever-increasing number of gross bodily diseases that are being attributed to mental stress. I should like, if I may, to offer the simpler explanation that patients in bed at home are generally less ill than their fellow sufferers in hospital. It is the illness, and not the associated but purely coincidental recumbency, that is the precursor of phlebothrombosis.

When a *person* becomes a *patient* many things happen—one of which must be the cause of phlebothrombosis. Most workers agree that it is the venous stasis in his legs; Mr. Stoker thinks it is the mental stress; I have suggested[1] that it might be the filling of his veins with irritating products of tissue breakdown. Time will show which, if any, of these hypotheses is correct, but it is interesting to see that the solitary patient described by Mr. Stoker (*a*) was gravely ill, (*b*) was fully ambulant, and (*c*) had lost a lot of weight.

A tremendous amount of painstaking work has gone into proving the very reasonable assumption that the axial stream in the leg veins is slowed down by recumbency. No work at all has gone into proving that this stasis causes clotting of the blood, although many workers, including Lister himself, have carried out experiments purporting to show that it does not. It may be opportune to draw attention once again to that forgotten but uncurdled moiety of our life blood which remains relatively stagnant whether we are in hospital or at home, sick or well, asleep or running for a bus.

INFECTIOUSNESS OF COMMUNICABLE DISEASES

SIR,—May I reply to the valuable critical letter from Dr. Bradshaw (Oct. 4).

The effect of some of the variables he mentions has in fact been investigated, but there is a limit both to the patience of non-specialist readers and to the forbearance of editors. A full account would have necessitated a paper of formidable dimensions. The material chosen for publication (Sept. 20) was limited to what was considered necessary to make the principles and methods clear enough for others to be able to corroborate, correct, and extend these studies. I am accordingly grateful for the opportunity to deal with some of the difficulties, although the discussion of them in the space of a letter may prove inadequate.

The Effect of Age

When our figures are broken down into single years of age they show approximately the same relative infectiousness for the three diseases at each age. The most serious disturbing influence is the immunity conferred on newborn infants by their mothers. This cuts down by more than a half the susceptibility to infection with measles or chickenpox in the child of less than one year of age, and the group is sufficiently big to have a perceptible effect on the final figure for infectiousness. There is, therefore, a good case for leaving out this group though we have in fact included it.

Composition of the Families

The majority of the mumps families feature in the chickenpox studies, and most of the chickenpox families occur again in the measles studies. In this respect we were very fortunate in that it ensures that the home conditions in the studies of the three diseases were similar. It also ensures, however, that the composition of the families as regards both age and numbers of susceptibles will differ especially for mumps owing to the effect of the different degree of infectiousness. In table I, for example, one finds relatively fewer families with only one susceptible at risk in the mumps study.

TABLE I—NUMBER OF FAMILIES ACCORDING TO THEIR CONTENT OF SUSCEPTIBLES AT RISK

Susceptibles at risk	No. of households		
	Measles	Varicella	Mumps
1	140	104	78
2	34	40	40
3	9	16	27
4	4	1	8
More than 4	..	2	4

It is well known that the incidence and age-distribution of these diseases tends to be different in rural and urban areas. It is therefore of particular interest that the homes in urban areas show almost the same attack-rate for all of the diseases as the homes in rural areas (see table II).

TABLE II—INFECTIOUSNESS IN URBAN AND RURAL HOUSEHOLDS

Infectiousness	Measles	Varicella	Mumps
Rural :			
Exposures	136	171	152
Transmissions	104	69	42
Rate	76·5 %	59·6 %	27·6 %
Urban :			
Exposures	130	112	39
Transmissions	97	71	10
Rate	74·6 %	63·4 %	25·6 %

On the whole there seem to be good grounds for hoping that the method described in the paper gives a fairly stable figure for infectiousness. When the larger groupings are broken down for analysis into small groups—as, for example, in the seasonal studies and in studying the attack-rate at different ages and in urban and rural homes—the same relative infectiousness is found in the three diseases. It is probably justifiable, therefore, to continue to use the method to study the epidemiological importance of the many influences that affect the spread and distribution of these and similar diseases in different sorts of community.

Epidemiological Research Unit,
Cirencester. R. E. HOPE SIMPSON.

THE SAFE HEARTH

SIR,—The coal fire-guard illustrated in the Birmingham leaflet, *Advice on Fireguards*, mentioned in your issue of Oct. 4 (p. 689), was designed by one of our members, Mrs. Darcy Braddell, and is being shown by us all over the country. Our constituent women's organisations, with a membership of over 2 million, are greatly concerned at the high rate and serious consequences of burning accidents due to unguarded fires. Anyone interested can see the guard in our offices at 18, South Molton Street, London, W.1. We particularly welcome all those associated with children's and old people's welfare.

Women's Advisory Council
on Solid Fuel. ELSPET FRASER-STEPHEN
General Secretary.

A CHEAP SURGEONS' CAP

SIR,—Mr. John Howkins (Sept. 27) described a cheap and comfortable surgeons' cap, and he included a photograph in which the surgeon was shown with hair and ears exposed. Mr. John Whittingdale (Oct. 4) evidently objects to the photograph, and recounts that Sir Holburt Waring insisted on hair being completely covered—an insistence which is in line with present-day knowledge. Unless Mr. Howkins's stockinette cap is also comfortable when covering the ears and all the hair, it cannot be regarded as an effective head-dress for an aseptic operation. I have yet to find a cap to equal that made by Robinsons of Chesterfield for wearing with their 'Cestra' mask.

These letters raise the larger question of aseptic technique with which every surgeon is inevitably concerned—a question which can be answered better by bacteriology than by the vague generalisations of Mr. I. A. McGregor (Oct. 11). Some of my colleagues and I, while visiting hospitals in England and abroad, have noticed a widespread slackness in aseptic technique in operating-theatres. It is by applying our knowledge of bacteriology to the subject that this deplorable tendency can be arrested and remedied.

We know that the bacteria which may infect surgical wounds have no power of movement themselves; but they can be projected into a wound on droplets from the noses and throats of people present, and they can be carried on particles of dust. Dust may enter operating-theatres on the clothes and footwear of attendants, on blankets, and in other ways; it may also fall from the hair and ears of those leaning over the operation area. It would be of great interest to operating surgeons to learn, through your columns, whether there is any operating-theatre in this country in which everybody wears an impervious mask over nose and mouth, in which the scrubbed-up staff have hair and ears completely enclosed, and in which all staff and patients completely change or cover their dust-laden clothing and footwear in an anteroom, so that as little dust as possible is brought into the operating-theatre. If there is an operating-theatre which is run on these lines every day of the week, it would be of great value if we could know the incidence of infection in the wounds of its clean cases.

London, W.1. ALISTAIR GUNN.

CURE OF TOBACCO-SMOKING

SIR,—Dr. Lennox Johnston's article (Sept. 6) and the subsequent correspondence are of great interest and considerable importance. The disease, as stated, is pandemic and the cure is not easy for many reasons. As one who was addicted to 35 cigarettes a day for 30 years I write with feeling!

However, I am convinced that the majority of people can get rid of this addiction if they realise it is harmful and that they will be able to face both the major and minor problems of life at least as well without a cigarette. A quiet determination to abstain, associated with having a cigarette available in the pocket, to avoid a panic search throughout the whole house, were my two best aids in the early days of complete abstention.

The main difficulty is that the risks of smoking are being purposely kept from the public today. The chief risk is cancer of the lung. In this country in 1951 more people died of this condition than from tuberculosis. A close association has been proved beyond any doubt. If such a close association had been shown between rapidly increasing cancer and any other social phenomenon publicity would have been nation-wide.

Many powerful bodies have a vested interest in playing down such publicity. The Treasury is foremost in this respect because it receives £610 million yearly from the tobacco tax. The national press is interested in revenue from advertisements, and the cinemas are also recipients of advertising revenue from the tobacco companies. One of the pleasures of being in the Services is that tobacco is less expensive. I understand the American Forces are supplied with large numbers of cigarettes free each week; thus we have the big battalions on the side of the pandemic condition.

A reasoned statement about the ill effects of tobacco is rarely given to the public. I doubt if my own experiences have been exceptional—my father developed cancer of the lung after 55 years of fairly heavy smoking; my father-in-law developed cancer of the lung after 50 years of heavy smoking; while my chief, a senior medical administrator, developed this condition after 40 years of smoking. These three deaths occurred within 18 months. In my own medical wards I have never less than three or four cases of this condition at any one time. Careful investigation constantly shows that they have been heavy smokers, while the work of Bradford Hill and Doll gives statistical confirmation of these clinical impressions.

The reports of the medical officers of health for Wembley and Willesden, areas served by this hospital, show that in 1951 more than twice as many people died from cancer of the lung as from pulmonary tuberculosis. This situation is becoming so serious that we cannot allow it to continue without emphatic protest.

Central Middlesex Hospital,
London, N.W.10. HORACE JOULES.

SIR,—I think we have a lot to learn from a group of addicts who have found a cure that works in many cases after the complete failure of medical treatment, exhortation, spiritual counsel, and so on: I mean Alcoholics Anonymous. By their anonymity, members of this group are protected from the pressure often applied by the uncured and from many other difficulties. They do not say that they will stop drinking next week, or that they will never drink again, or that they will try it again after a while. All they need think of is "not today," and they have found that this works best.

I suggest, therefore, that smokers who feel that it might be a good thing to stop should announce their intentions to nobody until the craving has really gone. It is difficult to say "not today" when one wants to smoke, but surprisingly easy to say "not now." It can be tried as an experiment, to see how long it keeps the craving from becoming intense. If curious friends inquire, one can put them off with a vague remark such as "been smoking too much lately."

I suggest that those who are smoking too much, and know it, try this method. I see no point in putting one's honour or self-respect to the test, and suffering needlessly, until this way has been tried. Many who try it out of pure curiosity will be surprised.

TOBACCO-ADDICT ANONYMOUS.

OTITIS EXTERNA

SIR,—For the past fifteen years in my own experience otitis externa due to a fungus infection has been a rarity in this country, and I am sure it is generally believed that the condition is a bacterial one. In many cases there is an underlying seborrhœic tendency, and any form of treatment in this type of case, whether successful or not, still leaves behind the constitutional condition, and therefore a tendency to recurrent attacks. Local applications should be of as benign a character as possible, as the skin rapidly becomes sensitive to chemicals of any kind. Some of the worst cases of external otitis one sees are almost certainly the result of ill-advised and too active treatment. In this category must be placed watery and oily preparations of the more recent antibiotic drugs. Penicillin drops are undoubtedly a common cause of persisting unhealed external otitis, and it is to be feared that chloramphenicol and terramycin will accompany penicillin in this unhappy position.

Knowledge of the character of the organisms present is by no means the only factor, and treatment in the sense of killing off these organisms is not necessarily the best means of achieving a successful result. Careful and clean removal of debris and unhealthy skin is at least as important, and attention to the scalp is perhaps even more so.

I cannot help regarding with considerable fear the "plugging" to which the profession is now being subjected of preparations containing the newer antibiotics for use on eczematous surfaces. It is true that your annotation last week also indicates some such attitude, but I personally could have wished it put more prominently and with a stronger emphasis. The indiscriminate use of these antibiotic preparations will almost certainly create as many problems as they solve—at a fantastic financial cost.

London, W.1. MAXWELL ELLIS.

SIR,—I feel that your annotation calls for some comment.

You cite Singer et al. as stating that this irritating disorder is usually caused by bacterial infection with *Pseudomonas pyocyanea*. The following points are against this supposition:

1. *Ps. pyocyanea* can usually be grown from any moist skin lesion, being especially common in cultures taken from chronic leg ulcers in patients attending the leg clinic of a skin department.

2. The treatment of external otitis by local antibiotics and especially chloramphenicol is usually quite unsuccessful, even when the organism has been shown to be sensitive to the antibiotic. Not infrequently the condition is worsened by such treatment.

3. The cause of external otitis is in nearly all cases an interference phenomenon. Thus a mild original itch receives undue interference, and *stimulation* of the wax glands by such interference produces an unduly sticky waxy secretion which fails to dry and drop out as do the normal ear secretions. This sticky substance forms an excellent culture medium for *Ps. pyocyanea* and other organisms.

4. I have never seen a case of external otitis which cannot be cured by proper firm packing of the ear daily with gauze

tape moistened with glycerin and ichthyol performed by an efficient outpatient sister. Alcohol, however, must be avoided absolutely. This method acts as a splint to reduce the œdema of the meatal wall and prevents access of the patient's fingers to a large extent. This method should always be combined with adequate wrist splinting at night, as the patient commonly attacks the ears during sleep. Fractional X-ray therapy, though of value in relieving the itching, is a small and inessential part of the treatment. The only cases in which this method is not successful are those of such chronicity that secondary stenosis of the orifice and chronic lymphangitis have supervened.

5. A further point indicating the interference nature of this disease *is the frequent association of Bact. coli* with *Ps. pyocyanea* and other organisms in cultures from the ear.

Sunderland. P. INMAN.

NEW OUTLOOK ON MENTAL DISEASES

SIR,—In your review (Oct. 4) of this book by Dr. Pickworth you praise him for his morphological study of the smaller blood-vessels of the brain and for pursuing original and unaccepted ideas about the cause of mental disease.

I think that a more sympathetic view of these ideas is justified than you express. You state that Dr. Pickworth has left the highroad of contemporary thought about the pathology of mental diseases; but, surely, the only thing that is agreed about the understanding of mental diseases and their pathology is that there is no highway known that leads to it. This is the only conclusion that can be drawn from the bewilderment expressed at a conference held by the Mental Health Research Fund this year and from the many methods of investigation which were suggested there.

In my opinion, Dr. Pickworth's hypothesis that reaction to infection has a much larger part than we realise in mental disease has much to support it. For instance, we believe that serious mental disease of almost any form may be caused by almost any infectious disease; it is common personal knowledge to all that the minor sinusitis associated with a cold in the head often produces distinct impairment of mental functions; the cure of severe mental disease after cure of long-standing infection, as recorded by Dr. Pickworth and Dr. T. C. Graves and others, is very impressive; and Dr. Pickworth's suggestion that alterations in local blood-supply of the brain may cause abnormalities in cerebral function is supported by our knowledge of the confusion of senses and thoughts during recovery from fainting. What is needed is a fuller understanding than we possess of the action of infection in chronic forms.

London, W.1. J. M. ALSTON.

THE NOTIFICATION OF DISEASE

SIR,—In his article in your issue of Oct. 11, Dr. E. D. Irvine rightly stresses that to be effective for control purposes notification must be statutory, since informal notification is almost necessarily incomplete. He then poses the question "Who can doubt that more accurate information will be obtainable in Manchester, where german measles is notifiable, on the effect of this disease in pregnancy than will be obtained by the voluntary inquiry now being made in regard to this and other diseases by the Medical Research Council?" Personally, being in charge of the inquiries made under the Medical Research Council, I can see no reason whatever to suppose that they will lack accuracy for the reason put forward by Dr. Irvine. They are not, in fact, dependent upon "voluntary inquiry."

Valuable information, though on a small scale, can clearly be obtained in Manchester from the notifications made to the medical officer of health *if* each reported attack in an adult woman is followed up to see whether she was pregnant at the time and, if so, whether she had a normal baby.

My own inquiries are also limited geographically—broadly to London and the Midlands—but they are based upon neither statutory nor informal notifications of the kind Dr. Irvine is discussing. Within these regions I am informed by the chief medical officer to the Ministry of National Insurance of the occurrence of each "double event" in an employed woman. The "double event" comprises: (1) the medically certified occurrence of german measles (or other specified disease) in such a woman; and (2) the subsequent birth of a baby within 12 months of the illness, as known by the claim to maternity benefit. Such mothers are then visited by one of my medical colleagues who examines the baby. (I have deliberately excluded the study of abortions.) With the coöperation of the general practitioners concerned, freely and invariably given, my colleagues in this work have experienced no difficulties in visiting all these babies.

We may well fail to collect enough data by these means, for the "double" is a relatively rare event. I do not believe we shall fail for the reason Dr. Irvi has in mind because it is not relevant. Possibly he merely confusing these inquiries under the Medic Research Council with the concurrent inquiries bei made by the General Register Office through medic officers of health.

and Tropical Medicine,
London, W.C.1.

A. BRADFORD HILL.

Public Health

THE SANITARY INSPECTOR

AT their annual conference at Brighton last mont members of the Sanitary Inspectors' Association aga made clear their conviction that they have now grow to full stature, and their impatience to occupy, manag and improve their estate—even to change its name and define its boundaries more acceptably. Their wish f independence and betterment is a sign of profession restlessness, proper and understandable in a vigoro body of men who have been on the go for the past eigh years, and present-day changes in the pattern of publi health administration offer them a fair opportunity to state their case.

PAST ACHIEVEMENTS

The Public Health Act of 1872 was the outcome of the mid-19th-century outcry for cleaner streets, more wholesome houses, purer water, and better disposal of refuse and sewage. This Act authorised the first appointment by local sanitary authorities of "inspectors of nuisances," and this title remained unchanged until 1921, when the Public Health (Officers) Act substituted for it the new name of "sanitary inspector." Although the work of sanitary inspectors has widened to include food inspection and sampling, infectious-diseases control, slum clearance, factory hygiene, and diseases of animals, the public still sometimes associate the designation "sanitary inspector" with drains and their imperfections.

For the first forty years of this century the sanitary inspector was reasonably content to be the trusted right-hand man of the medical officer of health—his expert executive and technical adviser on drainage, domestic sanitation and hygiene, food and drug sampling, meat inspection, and so on. In most public-health departments a modus vivendi developed whereby the inspector discussed his findings with the medical officer of health and they agreed together what action should be taken. Most of the day-to-day work was usually left entirely to the inspector. Today, in some towns the chief inspector makes his reports to the medical officer of health, who in turn reports to the appropriate committee of the local authority. In others, the chief inspector makes some reports directly to the public-health committee and receives their instructions. Direct responsibility depends mainly on the breadth of the inspector's duties. He may, for instance, be in charge of such services as disposal of domestic refuse, inspection of fresh meat, rat-catching, or sampling of fertiliser and feeding-stuffs. It depends even more on the attitude of the medical officer of health, to whose "general direction" the sanitary inspector is by ministerial regulation subject.

The modern inspector has travelled a long way in training and practice since Chadwick first conceived him as the field worker who inspected nuisances for the medical officer of health. It is understandable that he now feels ready to use his skill in a more mature way by assuming full responsibility for planning, proposing, and operating policy in local matters of hygiene. Chief sanitary inspectors chafe at the restrictions or inhibitions implied, and perhaps too often manifest, in the proviso "subject to the general direction of the Medical Officer of Health."

PRESENT DISCONTENTS

The sanitary inspector would, therefore, like to exchange this title for a more euphonious and savoury designation. "Sanitation," he says, is no longer his most absorbing interest, and "inspector" is too suggestive of snooping. But so far he has not been able to suggest a better name for himself. He regards as unjust and inadequate the present practice of fixing sanitary inspectors' salary scales according to those of other local-authority "administrative, technical and clerical officers," and the association calls for more appropriate national scales negotiated on the lines of those for public-health doctors and nurses.

Training and qualification is another bone of contention. At present the statutory essential first qualification is the certificate of the Royal Sanitary Institute and Sanitary Inspectors' Examination Joint Board. The association, with a membership of some 4000, thinks that its representation, and therefore its influence, on this training and examining body is inadequate.

But the crux of the inspector's discontent is his status. The general council of the association has asked [1] for the establishment of a single type of local sanitary authority to deal with all matters of environmental hygiene and to be responsible to a suggested "Sanitary Services Division" at the Ministry of Health. The local authority's chief sanitary inspector—so the association argues—should acquire, with his new name, complete independence of any medical officer of health and should be directly responsible to his employing authority for the efficiency of the new department, of which he would now become chief officer.

FUTURE PITFALLS

While there is undoubted logic shining through the equally undoubted discontent which inspires this proposal, the association perhaps does not appreciate sufficiently the risks of pressing for the withdrawal of the sanitarians from the public-health team. In trying to escape from the domination of the medical officer of health, sanitary inspectors might fall into other, perhaps less sympathetic, hands. Local authorities are loth nowadays to create new chief-officer posts and departments. A demand for change of title, status, and duties on the part of sanitary inspectors might well be used by some local authorities as an opportunity to transfer them from the health department to that of the engineer or surveyor. Indeed in many of the small local sanitary authorities, the engineer and surveyor's duties are already combined with the chief sanitary inspector's. Nor can there be any guarantee that future officers sequestrated from the public-health department will necessarily receive the improved rank and pay accorded to many of the doctors and clerks transferred in 1948 to the newly formed regional hospital boards. Instead further fragmentation of the public-health service might lead to the appointment of a lay administrator to supervise and coördinate the work of medical, sanitary, children's, and welfare officers.

At the request of the Sanitary Inspectors' Association the Ministry of Health last year set up a Working Party to study "the nature of the work at present being undertaken by Sanitary Inspectors; the nature and functioning of the present arrangements for their recruitment, training and qualifications and the adequacy of such arrangements." The evidence submitted by the association has not yet been published, but the Society of Medical Officers of Health in their evidence [2] insisted that, as sanitary inspectors are concerned with environmental health, they belong to the group of health workers who enjoy reasonable individual freedom in their work but are under the general direction of the medical officer of health. Only thus, says the memorandum, is it possible to ensure that the medical officer of health shall—as required by regulation—"inform himself respecting all matters affecting or likely to affect the public health in the district, and be prepared to advise the Local Authority on such matters." As the purpose of all sanitary business is to conserve the public health, the medical officer of health in the rôle of preventive physician would seem to be the specialist best fitted to pronounce whether aims have been achieved or are correctly directed.

Whatever the outcome of the Working Party's deliberations there can be little doubt that to separate the specialist sanitarian (by whatever name) from the public-health department would be a retrograde move. There can be even less doubt that a chief sanitary inspector merits from his medical officer of health the recognition and consideration due to a mature specialist colleague.

The Second Quarter in Scotland

In Scotland during the June quarter of this year [3] the birth-rate was 18·5 per 1000 population, which was 0·6 below the rate for the corresponding quarter of 1951 and 1·9 below the average for the corresponding quarters of the last five years. The stillbirth-rate was 25 per 1000 total births. The death-rate was 11·2 per 1000 population; this was 0·9 less than in the corresponding quarter of 1951. The infant-mortality rate was 34 per 1000 registered live births—1 less than in the corresponding quarter of 1951. The neonatal death-rate was 22 per 1000 live births, which was the same as in the corresponding quarter of 1951. The death-rate from all forms of tuberculosis was 30 per 100,000 population (compared with 39 in the corresponding quarter last year), comprising 25 (33) from respiratory tuberculosis and 5 (6) from other forms.

Books Infected by Scarlet-fever Patients

In his annual report for 1951, Dr. E. K. Macdonald, medical officer of health for Leicester, refers to an investigation in that city to establish the likelihood of patients with scarlet fever transmitting infection to others through library books. The inquiry was undertaken by Dr. A. I. Ross, deputy M.O.H., in conjunction with Dr. E. H. Gillespie, director of the Public Health Laboratory, Leicester.

Arrangements were made that when a patient found to have scarlet fever had a library book this should be examined bacteriologically, and swabs should be taken of the patient's nose and throat. As a control, books from patients with Sonne dysentery were also investigated.

---

[1] *Sanitarian*, 1949, 58, 85.

[2] *Publ. Hlth*, 1952, 65, 137.

[3] Quarterly Return of the Registrar-General, Scotland: Births, Deaths and Marriages Registered in the Quarter ended June 30, 1952. H.M. Stationery Office. Pp. 30. 2s. 6d.

With the inquiry almost complete, 141 books had been examined—91 from patients with scarlet fever and 50 from patients with dysentery. In the scarlet-fever group streptococci of the same serological type were found in both patient and book in 18 cases (19·8%). In the control series a streptococcus was recovered from the book in only 3 instances (6%).

"It is thus evident," says Dr. Macdonald, "that there is a significant difference in the number of times streptococci were recovered from books which had been in contact with scarlet fever compared with those in the control series. This shows that it is possible for books from scarlet fever patients to spread infection and that, therefore, appropriate measures such as disinfection or destruction to deal with them should be continued."

A full account of the investigation is to appear elsewhere.

River Pollution

"I love," wrote Izaak Walton, "any discourse of rivers and fish and fishing." Even those who are not, in his familiar phrase, "Brothers of the Angle" can sympathise with a fisherman's desire that our rivers should not be so foul as to spoil his sport. The Anglers' Co-operative Association has just issued a new edition of what it calls its Pollution Handbook,[1] indicating amongst other things the change made by the Act of 1951.

Previously there had been only one legal definition of pollution. It was the same for the purposes of the Public Health Acts and the Rivers Pollution Prevention Act and for the purpose of proceedings in a civil court for damages or an injunction. Henceforth the requirements are different for criminal and civil proceedings. The criminal offence will ordinarily arise from the discharge of an effluent which violates a standard prescribed by the by-laws of a river board "determining when matter is to be treated as poisonous, noxious or polluting for the purposes of the Act." For the purpose of civil proceedings, on the other hand, pollution will still be judged by what the courts recognise as the common-law rights of a riparian owner—i.e., his right to have the water which passes his property in its natural state unaltered in quality, temperature, or volume.

River water, the handbook explains, is not pure H_2O but a very dilute solution of many different chemicals, including dissolved oxygen. Any alteration in the amounts or proportions of those chemicals, or any addition or subtraction, may alter the quality. There may be additive pollution through the introduction of directly deleterious substances like cyanide, chlorine, arsenic, ammonia, acids, lime, or oil. There may be subtractive pollution such as removes or absorbs the oxygen—for example, by the discharge of hot water or of effluents containing putrefying matter from sewage works, sugar-beet factories, or paper or silk mills. There may be changes in appearance and smell. "Innocuous discoloration" was not an offence under the now substantially repealed Act of 1876; it is not necessarily an offence under the new Act, though section 5 enacts that the standards prescribed by river-board by-laws may take into account both temperature and the effect of discoloration. The handbook doubts whether discoloration can ever be quite innocuous from a fisherman's point of view because, by shutting off sunlight, it must affect the algæ on which insect life depends. Discoloured water is not the water in a natural state to which a riparian owner is entitled. Finally, there is bacterial pollution which may render the water unsafe for drinking, bathing, the growing of watercress, and other purposes. Here the A.C.A. concedes that scientific research is still needed if the danger to fish is to be exactly assessed.

It seems reasonable to assume, as Izaak Walton would doubtless have done, that what is harmful to mankind is harmful to fish, and vice versa. At any rate in the campaign for cleaner rivers the interests of public health and of angling coincide.

Obituary

HERBERT ELDON ROAF

M.D. Toronto, D.Sc. Lpool.

Professor Roaf, who died on Sept. 21, was a Canadian by birth and education, but as a welcome immigrant to this country he had held chairs of physiology at the London Hospital and at the University of Liverpool.

He was born in Toronto in 1881, the son of the late James R. Roaf, K.C. From the Upper Canada College in Toronto he went to the university of that city, where he graduated in medicine in 1902. In the same year, with a Johnston Colonial fellowship, he came to this country to work under Benjamin Moore at Liverpool. In 1904 he took the Conjoint qualification and the following year his M.D. degree. In 1906 he became assistant lecturer in the department of physiology under Sherrington, and in 1909 he was appointed lecturer in chemical physiology. In 1909 he graduated M.SC. at the adopted university where he had settled so happily, and in 1910 he proceeded to the D.SC.

In 1911 he came to London to take up the lectureship in physiology at St. Mary's Hospital Medical School. He held this post till 1920 when he was appointed to the chair of physiology at the London Hospital. Shortly afterwards he produced his book on *Biological Chemistry* which many found to be a readable introduction to biochemistry. In 1932 he returned to Liverpool on his appointment to the George Holt chair of physiology which he held until 1944. On his retirement he received the title of professor emeritus.

During the late war, besides bearing a heavy load of departmental work, Roaf carried out research on vision for the Admiralty. He was the right man to undertake this task, for during his working life as a scientist the problems of colour-vision had always been one of his chief interests. But he was not a narrow specialist, and the breadth of his outlook was shown by his methods as a teacher. It was his practice to introduce his students to physiology by lines already made familiar to them by their study of the preliminary sciences. Thus the physics of the body—movement, respiration, and electrical changes of the heart—led on to the chemistry of organs and their processes, till the students had learned something of almost every system of the body and yet been asked to do little more than apply knowledge they already possessed. Roaf also followed this approach in his *Textbook of Physiology*, of which a second edition appeared in 1936.

Of Roaf's personal qualities R. C. writes: "He was a gentle and indeed a shy man, the soul of integrity and endowed with high ideals of thought and conduct. These expressed themselves in quiet ways—a modesty which did not prevent him from standing firm for a principle, a deep sense of personal responsibility to his students which led him and his wife to keep open house for them in their delightful home at Grassendale, a meticulousness of scientific approach, the satisfying enjoyment of doing his own gardening, and a devotion to his unobtrusive work as chairman of the church committee of the historic Ancient Chapel of Toxteth."

Professor Roaf married Beatrice Sophie, daughter of Sir William Herdman, F.R.S., and she survives him with two daughters and two sons, one of whom is an orthopædic surgeon in Liverpool.

JAMES COWAN WOODS

O.B.E., B.A. R.U.I., M.D. Lond.

Dr. Woods, who died on Sept. 24 at the age of 76, had been for many years lecturer in mental diseases at the London Hospital and at St. George's Hospital.

He was educated at the Royal School, Dungannon, Northern Ireland, and from an early age he wished to take up medicine as a career, but for some time this was impossible for financial reasons. He became, therefore, a schoolmaster, and in 1902 he obtained an honours degree in history at the Royal University of Ireland, where he was awarded an exhibition. Soon afterwards he was able to begin his medical studies at the London Hospital, where he qualified in 1907. Four years later he took his M.B., and in 1914 he was awarded the gold medal in psychiatry for his M.D. thesis. In 1917 he received the Gaskell gold medal and prize in psychology and psychological medicine. For his work during the first world war while in charge of the Special Hospital for Officers at Palace Green he was appointed O.B.E.

H. D. writes: "Caring little for sport in general, Woods was yet an enthusiastic follower and most capable exponent of boxing. Though never more than a lightweight, he successfully represented the London on at least one occasion in the middle-weight division of the inter-hospital competitions. A bachelor, of a singularly diffident and retiring nature, he devoted himself almost exclusively to the conduct of a large consulting practice, until the onset of his last illness in 1949 forced him to retire from active work."

JAMES AITKEN

M.B. Edin.

Dr. Aitken died on Oct. 2 at his home at Stanmore, where he had been in practice for over thirty years. He graduated in medicine at the University of Edinburgh in 1917, and he served in the 1914–18 war with the R.A.M.C. and in the late war with the R.A.F., where he rose to the rank of wing-commander.

S. H. writes: "Dr. Aitken was a man who exhibited the highest qualities which can be associated with a general practitioner, and after he settled at Stanmore he soon built up an excellent reputation. He was superintendent of the cottage hospital and one of its trustees, and under his guidance the hospital saw its best years. He felt a sense of personal loss when the exigencies of the National Health Service led to the conversion of the hospital into a home for the chronic sick. His death will be mourned by many, for he was entrenched deeply in the affections of all who knew him."

PHILIPP ELLINGER

M.D., D.Phil., F.R.I.C.

Dr. Ellinger, who died in London on Sept. 12, came from an old Jewish family that gave Germany several well-known scientists and prominent industrialists.

Born in Frankfort in 1887, he took his PH.D. in chemistry at Greifswald University before he began to study medicine at Munich and Heidelberg. At the pharmacological institute at Heidelberg he spent his most formative years as assistant, lecturer, "professor extraordinarius," and deputy director under Gottlieb, Wieland, and Heubner. In 1931 he was called to the professorial chair of pharmacology at the Medical Academy of Düsseldorf. Dismissed by the Nazis in 1933, he came to this country and in 1934 began work at the Lister Institute, where he was enabled to carry on his varied research projects until his retirement last June. To be free of administrative and teaching burdens suited him well, and in 1937 and 1938 he visited Egypt on behalf of the Medical Research Council to study pellagra and make therapeutic trials in pellagrins which seemed to be promising. Unfortunately, he fell ill during his second visit and he never entirely recovered his former robust physical health.

Ellinger's many contributions to physiology and pharmacology cover a wide field. His first papers dealt with carbon monoxide poisoning; but after a number of other studies in toxicology, he turned to physiology and he began to investigate renal function. The formation of urine, the site of acidification of urine, and the urinary excretion of chlorides in acromegaly were some of the problems he attacked successfully, using his own technique of intravitam microscopy. In this country he is best known for his work on the biosynthesis of nicotinic acid and nicotinamide in the human intestine, on deficiency following the administration of penicillin, and on the effect of liver poisons on the elimination of nicotinamide. In 1949 he was able to show that, in the mouse, high nicotinamide elimination was genetically controlled and probably due to a hereditary recessive character.

A colleague writes: "Ellinger's strength as a research-worker and investigator was based on his comprehensive knowledge of biology and its supporting sciences, which he combined with a lively interest in clinical medicine. Moreover, he had a special flair for the critical assessment of research methods. He not only found ways and means and designed apparatus for his own work, but ungrudgingly advised anyone who asked his help, on the possibilities as well as the difficulties and pitfalls of the way. His judgment of men and of affairs was always reliable: it was founded on an unbending belief in the high responsibility of the scientific worker. His opinion, often critical, but never unjust, was highly respected at the meetings of the physiological, biochemical, and pharmacological societies of which he was a member. He loved Britain and the British way of life and he was happy that his children could grow up in these islands. But it gave him great satisfaction when in 1950 the Düsseldorf Academy invited him to return to his professorial chair and, when he declined, made him an honorary member."

Dr. Ellinger is survived by his wife, one daughter, and two sons.

Appointments

Bolsover, G. D., B.M. Oxfd: appointed factory doctor, Eynsham, Oxfordshire.

Frew, J. F. M., M.B. Glasg., F.R.C.S.E.: consultant in orthopædic surgery, Northern Regional Hospital Board, Scotland.

Gerlis, L. M., M.B. Lond.: asst. pathologist, central laboratory, Grimsby General Hospital.

Hollis, P. W. T., M.B. Lond.: asst. director, mass-radiography units, Bristol.

Jermiah, D. E., M.B. Madras: asst. M.O.H. and asst. school M.O., Salford.

Lawy, H. S., M.D. Bagdad, L.M.S.S.A.: asst. pathologist, central laboratory, Grimsby General Hospital.

Mackenzie, R. M., M.B. Lond., D.A.: consultant in anæsthetics, Scarborough, Bridlington, Malton and Whitby H.M.C.

MacLeod, Mary, M.B. N.U.I.: asst. psychiatrist (S.H.M.O.), Naburn and Bootham Park Hospital, York.

Pleydell, M. J., M.D. Lond., D.P.H.: deputy M.O.H. and deputy school M.O., Northamptonshire.

Roberts, T. B. L., M.R.C.S., D.A.: anæsthetist, Maida Vale Hospital for Nervous Diseases, London.

Rosie, J. M., M.D. Glasg., D.P.M.: consultant psychiatrist and deputy medical superintendent, Craig Dunain Hospital, Inverness.

Trapps, N. C. B., M.R.C.S., D.A.: anæsthetist, Maida Vale Hospital for Nervous Diseases, London.

Yeates, W. Keith, M.D., M.S. Durh., F.R.C.S.: consultant surgeon (asst.), urological department, Newcastle General Hospital.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Births, Marriages, and Deaths

BIRTHS

Barrett.—On Oct. 6, to Phyllis Eileen (née Batchelor), wife of Dr. G. M. Barrett, of Lancaster—a son.

Henderson.—On Oct. 9, at Meadstead House, Royston, near Barnsley, to Winifred (née Hale), wife of Dr. James Henderson—a daughter.

Hirst.—On Oct. 7, at Oldham, to Dr. Stella Armitage (née Speight), wife of Dr. John Hirst—a daughter.

McMillan.—On Oct. 8, at Flore House, Northamptonshire, to Juliette, wife of Dr. James McMillan—a son.

O'Grady.—On Oct. 5, at the Middlesex Hospital, London, to Madeleine (née Becquart), wife of Dr. Francis O'Grady—a daughter.

Robinson.—On Oct. 9, at Warrington General Hospital, to Janet (née Callow), wife of Squadron-Leader K. F. Robinson, M.B.—a daughter.

Sinclair.—On Oct. 6, to Joyce, wife of Mr. S. R. Sinclair, F.R.C.S., 6, Adelaide Park, Belfast—a daughter.

MARRIAGES

Gibson—Galbraith.—On Oct. 11, in Glasgow, Eric Osborne Gibson, M.B., to Cynthia Graeme Dunlop Galbraith.

Yealland—Simpson.—On Oct. 4, Michael Yealland, M.R.C.P., to Susan Simpson, M.B.

DEATHS

Ashby.—On Oct. 9, at 3, Lancaster Road, Didsbury, Manchester, Hugh Tuke Ashby, M.D. Camb., F.R.C.P., aged 72.

Cogswell.—On Oct. 12, at Red Roofs, Sidmouth, Devon, Philip Dare Cogswell, M.R.C.S., late of *Bromley, Kent.*

Coombes.—On Oct. 7, at Croft Cottage, Horsebridge, Sussex, Percival Charles Coombes, M.R.C.S.

Finny.—On Oct. 10, at 41, Liverpool Road, Kingston Hill, Surrey, William Evelyn St. Lawrence Finny, M.D. Belf., M.CH. R.U.I., J.P., barrister-at-law, Inner Temple, high steward and honorary freeman of the royal borough of Kingston-upon-Thames, aged 88.

Hobbs.—On Oct. 8, at Benghazi, Anthony Arthur Hobbs, M.R.C.S., captain, R.A.M.C., aged 26.

Lawson.—On Oct. 8, at 12, Ovington Court, London, Frederick James Lawson, M.B. Lond.

Wade.—On Oct. 5, Richard Ramsden Wade, M.A., D.M. Oxfd, of The Little House, Hindhead.

Notes and News

RESEARCH AT THE R.C.S.

AFTER the monthly dinner of the Royal College of Surgeons of England on Oct. 8 visitors were able to explore the departments of anatomy, physiology, and pathology, and to see some of the demonstrations and exhibits that had been set out; but it was impossible to get round quickly enough to see all the work that is going on at the college and at the Buckston Browne Research Farm.

In the department of anatomy, Prof. Gilbert Causey explained some of his work on nerve-fibres; he had taken a number of medullated fibres, given them a sharp pinch, and then cut sections of them to see what had happened. Immediately after compression, longitudinal sections showed a complete break in the myelin sheath, but within a few hours the myelin began to "flow" back again across the gap. In transverse sections the normally sharp outline of the sheath was destroyed and its contents emulsified, only for the phases to separate out a little later. These observations on the fluid properties of nerve-fibres recall the Cartesian idea of a physical flow along the nerve—an idea which may be by no means out of date and which may yet fit in with what is known about electrical and chemical changes in the nerve-fibre to give a fuller explanation of the working of the neurone as a whole. Professor Causey also demonstrated the results of rat experiments designed to trace what is usually called the intracellular phosphorus. Autoradiographs of nerve and muscle showed that atoms of the radioactive isotope P^{32} were taken up in the sheaths of the fibres and did not actually enter the cell at all. Dr. Frank Stansfield had been thinking how unreliable some textbook statements really are: for instance, it is often said that the paranasal sinuses are of little importance in preserving the correct balance of the head, because if the maxillary antra were replaced by bone the weight of the head would only be increased by 1%. Dr. Stansfield has shrewdly knocked the bottom out of this argument by a delightfully simple experiment which would convince the most unmechanically minded. He fixed a dried skull on a stand and connected a spring balance between the occiput and a point on the table beneath; the spring represented the occipital muscles, and the balance measured the tension in them. He then filled the maxillary antra with a substance of the same density as bone, and the balance promptly recorded a considerable increase in the tension of the hypothetical muscles—as, of course, he knew it would from a consideration of the mechanical moment of the added weight about the fulcrum on which the skull turns. In this respect at least, the part played by the sinuses in keeping our heads from nodding cannot be so easily dismissed.

On the floor above, in Prof. Geoffrey Hadfield's department of pathology, Dr. L. M. Franks showed how animal experiments have suggested that the anterior chamber of the eye is a promising site for heterologous transplants of malignant tumours; some tumours have survived and shown active mitosis after 10 weeks. Clearly, great advantages will be gained if this method can be extended to become a means of preserving and studying human tumours.

Prof. David Slome and his colleagues in the department of physiology and the research-workers at the Buckston Browne Farm also exhibited some of their work. For example, Dr. W. J. Dempster talked about experimental transplantation of the kidney; and Dr. I. K. R. McMillan illustrated his investigations into the action of the cardiac valves with a colour film in which post-mortem specimens were used to demonstrate the mechanics of normal and diseased aortic valves and the effect of operations designed to relieve stenosis or regurgitation. During the dinner technicians had been installing in the basement Dr. D. G. Melrose's new apparatus for maintaining an extracorporeal circulation in man. This pump-oxygenator of increased efficiency promises to give important help to the cardiac surgeon. Dr. Melrose suggested that the most profitable way of using the apparatus might be to combine it with a means of lowering the body-temperature and consequently the metabolic-rate; for under these circumstances complete cardiac arrest can be tolerated for long periods and the scope of surgery is correspondingly increased.

At the dinner the President, Sir Cecil Wakeley, was able to report that the worries of steel shortage no longer threatened to delay the first stage of the plan for the restoration and extension of the college. The great hall, the three Wellcome museums, the council room, exhibition hall, and cloakrooms come in the first part of the programme. Sir Cecil was hopeful that the progress of the next stage, which includes the building of the Nuffield College of Surgical Sciences, would soon be equally assured. The guests at the dinner included some distinguished visitors from America, and Sir Cecil told of the generous hospitality that they and their colleagues had given him during his recent travels. His toast brought responses from Prof. Howard Naffziger (San Francisco), Prof. Everett Evans (Richmond, Virginia), and Mr. M. J. Petty, F.R.C.S. (Buenos Aires).

THE MIDWIVES

THE old Central Midwives Board retired on March 31 of this year, and on April 1 the new board took over. This change, an outcome of the Midwives Amendment Act, 1950, and the new Midwives Act of 1951, has increased the size of the board from 14 to 16, and gives members three years of office instead of one. Our midwifery service has a very high tradition, and a vast membership. On March 31 of this year, according to the last report of the old board,[1] there were nearly 55,000 trained midwives on the roll, though, of course, only about a third of these (17,512) actually notified their intention of practising. The board are no longer under a statutory obligation to publish the complete roll for external circulation, and the only roll now published contains the names of practising midwives. As time goes on, the numbers on the roll decline of those who trained before 1939 when the present training rules came into action. They now represent less than half the total of midwives in practice.

The board were still inconvenienced, at the time of publication, by the fact that the Ministry of Health and the associations of local authorities had not yet agreed on a national arrangement for paying for the second period of training of pupil midwives. In some second-period training-schools the whole six months is spent on the district, and in those cases the local authority pays their fees without question. Usually, however, three months is spent on the district and three in hospital; and the hospital and local authorities have to settle the responsibility between them. Arrangements differ in different areas; and this makes some authorities cautious about opening districts for training. Births at home are getting scarcer, so if midwives are to get enough domiciliary experience new districts must be opened to them. The board think it urgent that some common system of payment should be arranged; and meanwhile ask local authorities not to let purely financial considerations prevent them from making their districts available for training.

The search for the perfect analgesic for use by midwives goes on. A new joint subcommittee, consisting of members of the analgesia in midwifery committee of the Medical Research Council, and of the anæsthetics committee of the Royal College of Obstetricians and Gynæcologists, with Dr. Albertine Winner of the Ministry of Health as secretary, has been appointed to direct clinical trials of new models of trichlorethylene inhalers. The board are represented on this subcommittee by Mr. Arnold Walker, F.R.C.O.G., their chairman. Meanwhile, pupil midwives, working single-handed, are allowed, when the teaching midwife judges them to have reached such a standard of competence as to be safely trusted with the responsibility, to administer nitrous-oxide/air analgesia.

OPINION ON PRESCRIBING

IN the view of Prof. David Campbell, president of the General Medical Council, prescribing in the National Health Service should be confined to official drugs and preparations. In an inaugural address at the School of Pharmacy, University of London, on Oct. 8, Professor Campbell suggested that such a policy would not impair but would in fact enhance efficiency, and it would be less expensive to the community. The danger now, he declared, was excessive and inaccurate medication; and this danger was not lessened by persistent advertisement in the form of quasi-scientific and clinical dissertations which were showered so freely on the medical profession by various manufacturing drug firms, often of the same drug under half a dozen or so different proprietary names.

"Many years ago," said Professor Campbell,[2] "Sollman maintained that one of the clamant needs of the medical profession in America was for some authoritative statement as to how to discriminate between good and bad in drug advertisement. That led to the establishment by the American Medical Association of the Council on Pharmacy and Chemistry and the annual publication of 'New and Non-Official Remedies' which tries to give reliable information as to the action and uses of new drugs. It may be that the National Formulary and the deliberations of the Cohen Committee will help to solve the problem in this country. But I doubt it. Now that we are to have a quinquennial publication of the British Pharmacopœia with Addenda in the years between, I suggest that it is worth considering whether, save for experimental purposes, prescribing in the National Health Service should be confined to drugs and preparations made official in the Pharmacopœia."

GENERAL PRACTICE TEACHING UNIT

The Rockefeller Foundation has made a grant of £25,000 to the University of Edinburgh for developing its general practice teaching unit. This unit, described in our columns two years ago by Dr. Richard Scott,[1] was created by the faculty of medicine to train senior medical students in general practice. It is a modern development of the dispensary training which has been a characteristic feature of the Edinburgh medical school for more than 150 years. The grant will be used to develop new techniques of training students, and to study the technical and clinical problems peculiar to general practice.

SUPPLIES OF TERRAMYCIN

A limited supply of 20 mg. vials of pure terramycin for sensitivity tests will shortly be available to hospital laboratories. Requests should be sent to the regional distribution centres from which terramycin is now supplied.

University of Oxford

Prof. T. Pomfret Kilner has been appointed to carry on the duties of the Nuffield professorship of surgery during Michaelmas term.

Prof. Dorothy Russell will deliver a Litchfield lecture at the Radcliffe Infirmary, Oxford, on Wednesday, Oct. 29, at 5 P.M. Her subject is to be Disturbances of Hypothalamic Function in Man.

University of Cambridge

On Oct. 1 Sir Lionel Whitby, master of Downing College and regius professor of physic in the university, was admitted to his second year of office as vice-chancellor.

University of St. Andrews

On Oct. 10 the degree of M.D. with honours was conferred on J. W. Smith.

Royal College of Surgeons of England

At a meeting of the council on Oct. 9, with Sir Cecil Wakeley, the president, in the chair, Mr. R. C. Davenport and Mr. F. C. W. Capps were admitted to the court of examiners to examine in ophthalmology and otolaryngology respectively for the fellowship. Sir Charles Symonds and Prof. Harold Dew (Sydney) were appointed the Sir Arthur Sims Commonwealth travelling professors for 1953. The first James Berry prize was awarded to Mr. R. H. C. Robins for his essay on the Treatment and Preservation of the Injured Hand. Dr. B. D. Wyke was appointed senior lecturer in the department of physiology. A Leverhulme Research scholarship was awarded to Mr. A. E. Kark (Witwatersrand). Mr. Brian Greenwood (St. Thomas's Hospital) was admitted as a Macloghlin scholar.

A diploma of fellowship was granted to G. S. Pestell and a diploma of membership to J. H. Swallow. The following diplomas were granted, jointly with the Royal College of Physicians, to the following candidates:

D.Phys.Med.—P. J. R. Nichols, J. G. Parish, R. C. Robb.

D.T.M.&H.—Soroj Kanto Ally, Georges Belios, K. H. Blaauw, Jo Bonne, Matilda J. Clerk, D. F. Clyde, K. R. J. Coates, K. J. Covell, J. C. Crook, J. S. Davis, Somabhai Chhakaddas Desai, S. S. Epstein, Henry Foster, D. G. Garrow, Anthony Gerada, S. R. S. Godkin, E. G. Hardy, J. R. Harries, Monica M. Hogben, Benson Okeke Igwebe, Gillian F. Jacob, P. A. H. Jenniskens, Elizabeth E. Johnson, Perin Kaikobad Jungalwalla, Tawfik Karadshy, Muhammad Khalaf, Muhammad Naim Khan, Abdel Razag Mubarak, Noi Panikbutra, Upali Kirthisiri Perera, Bhagwat Prasad, Sudhir Kumar Roy, Francis Saliba, W. B. Scale, D. H. Shennan, Shurvir Singh, A. W. Stinton, D. A. T. Tizard, R. A. R. Topping, Prasong Tuchinda, C. J. Xuereb.

D.C.H.—L. M. Armstrong, Harry Buckstein, J. F. J. Collins, June P. Cooper, Winifred Danaraj, B. M. Davies, Pamela Deas, G. L. de Silva, J. A. C. de Silva, Norman Feldman, Nellie P. Fernando, P. T. A. P. Fernando, Joan Ford, Yvette A. P. Franklin, O. P. Gray, Ruth F. Harris, W. L. F. Hatchuel, Frances M. Hill, Mary A. le C. Hills, Chandra Hooja, Pamela J. Houchin, W. W. Jones, Margaret Kennedy, Barbara Kilpatrick, C. W. Lankester, I. C. Lewis, Toan Keng Lim, Sampath Loganadan, Sudhindra Kumar Majumdar, Patricia A. Monk, E. A. Nieman, Olwyn K. Ockelford, D. J. A. L. Panditharatne, Dina Patuck, G. J. V. Perera, P. L. Pickering, Barbara M. Philpott, Quah Quee Guan, T. A. I. Rees, Frances L. J. Robinson, Pauline M. Seymour-Cole, Katherine A. H. Smith, Cheruvamky Srinivasan, June Stephenson, Gwendolyn R. Tapp, Frank Taylor, Nicolaas Van der Merwe.

D.I.H.—K. M. Basu, A. T. Halliday.

Yorkshire Association of Graduates of Glasgow University

The first post-war dinner of this association will be held in the Great Northern Hotel, Leeds, on Friday, Oct. 31, at 7.30 P.M., when Professor J. D. MacKie, LL.D., is to be the guest of honour. Further information may be had from the hon. secretary of the association, Dr. William MacAdam, 24, Park Square, Leeds.

Back Payments to General Practitioners

The Ministry of Health has asked executive councils "to make every endeavour to pay" on Nov. 28 the amounts of back remuneration due to doctors under the Danckwerts award (E.C.L. 77/52). Payment to doctors no longer on a council's list may be delayed, but it is hoped that all payments will be completed by March 31, 1953.

Charing Cross Hospital

At the annual prize-giving of the medical school on Oct. 10, Lord Inman, chairman of the board of governors, announced that the hospital had now signed the contract for its new site at Northwick Park, Harrow. The site had 47 acres, of which 34 were to be for the hospital and 13 for the medical school. "The plans are all ready," he continued, "and we hope it will not be long before the economic condition of the country will allow us to make a start on this great scheme for a new Charing Cross Hospital and its Medical School."

W.H.O. Regional Committee for Europe

This committee, which met in Lisbon on Sept. 25–27, has agreed that the main tasks in the next four years should be: (1) coördination of health policies and exchange of experience between national health administrations; (2) studies of existing health patterns and problems; and (3) an increase in the number of trained personnel in all categories of public-health work. The committee was informed of a "massive decrease" of venereal infection among the 80,000 boatmen on the Rhine River. The regional committee will hold its third session in Copenhagen in September, 1953. The regional office is to be provisionally maintained at Geneva for at least eleven months.

London Hospital Dinner

Sir John Parkinson, presiding over the old students' dinner on Oct. 9, began by speaking of some of the former Londoners who had died during the year—Hugh Cairns, Leonard Hill, Millais Culpin, H. E. Roaf, Garnett Passe, and Gordon Wilson. By retirement the hospital was regretfully losing S. P. Bedson and John Marrack, in whose chairs he welcomed C. F. Barwell and F. L. Warren. W. J. O'Donovan, who had achieved the seemingly impossible by proving himself as great a teacher as his predecessor Sequeira, had in turn been succeeded by Brian Russell; and other new appointments were those of S. D. K. Stride as assistant anæsthetist, and J. V. Crawford as assistant surgeon. Whether a hospital was governed by a house-committee or a board of governors, said Sir John, its essential workers were the doctors, who had been in existence before there was any kind of organisation and would outlast any of them. The reputation of the London was being extended not only by its teachers but also by the men in practice who take pride in their work and honour it by what they do. His own debt to the hospital could never be repaid: his pride in it was unbounded, and it had been to him a real and happy medical home. Sir Alun Rowlands, proposing The Chairman, conducted his hero from pastoral Lancashire (with side glances at the Universities of Liverpool on his right and Manchester on his left) via Bletchley (where he refrained from changing for Oxford or Cambridge), to Euston and so to University College. Continuing, after a year, his quest for the best of its kind, the young John Parkinson eventually reached the London Hospital, and proceeded to fulfil his early promise not only as a physician and leader in cardiology but incidentally as a painter in water-colours and a gardener of distinction. If, like the best novels, Sir Alun's narrative contained one or two extraneous characters and cheerful interpolations, these did not obscure the sincerity of his tribute. And both his respect and his friendship for the chairman were equally manifest in his audience.

---

[1] *Lancet*, 1950, ii, 695.

Lloyd Roberts Lecture

Mr. Bernard Darwin will deliver the Lloyd Roberts Lecture at the Royal Society of Medicine, 1, Wimpole Street, W.1, on Wednesday, Oct. 29, at 8.30 P.M. He will speak on Dickens's Doctors.

Christian Medical Fellowship

Sir Henry Holland will deliver a lecture to this fellowship on Wednesday, Oct. 22, at 8.15 P.M., at the Royal Empire Society, Northumberland Avenue, London, W.C.2. His title of his address is to be The Doctor—has he a Faith ?

Epsom and Sutton Inter-Hospital Psychiatric Association

This association will hold a meeting at Banstead Hospital, Sutton, on Thursday, Oct. 23, at 8 P.M. The programme of papers and clinical demonstrations will be preceded by the election of officers for 1952–53.

London Medical Exhibition

The exhibition will take place this year at the new hall of the Royal Horticultural Society, Greycoat Street, S.W.1, from Nov. 17 to 21, from 11.30 A.M. to 6.30 P.M. Sir Cecil Wakeley, P.R.C.S., will open the exhibition at noon on Nov. 17.

Presentation to Sir William Hume

On Oct. 7, past and present members of the medical staff of the Royal Victoria Infirmary, Newcastle upon Tyne, entertained Sir William Hume to dinner in honour of the knighthood conferred upon him. In presenting Sir William with a television set, Dr. S. Whately Davidson, chairman of the medical board of the hospital, said the company wished to express their continued and growing affection for one who during the past 50 years had been a "father" to so many of those present. "But for the great opportunities which Sir William gave us to obtain a wide experience and develop a sense of responsibility, by seeing and doing things for ourselves, I doubt whether many of us would be where we are today."

King's College Hospital

At the opening of the 123rd session of the medical school on Oct. 3, Mr. St. J. D. Buxton presided, and the inaugural address was given by Dr. F. M. R. Walshe, F.R.S. In presenting his report, Dr. V. F. Hall, the dean, said that a scheme of interchanges had been introduced by which senior registrars will receive part of their experience at regional board hospitals with the object of widening the experience of the future consultant. The requirement under the Medical Act, 1950, that house-appointments must be held for a year before registration would not mean any great change at King's, where it had been the custom for many years for most students to hold resident posts. It was possible that in its early stages the machinery of the new Act might produce delays and difficulties which would involve the individual in hardship, but he had no doubt that the scheme itself was excellent. A number of rooms in the hospital would soon be converted into research laboratories, and Dr. Hall hoped that by next October this new research unit would be in full activity. In addition the school had already equipped a room as a neurohistological and gynæcological research laboratory. A new joint hospital and medical school research committee had been established to examine all new research proposals, and both the hospital and the school had made available some additional funds for research. The several benefactions the school had received during the year included £35,000 from the estate of Surgeon Captain A. D. Cowburn, lately H.M. Coroner for the Southern District of the County of London. This was for research in pathology, bacteriology, morbid anatomy, and allied subjects.

CORRIGENDA: *Prolongation of Action of Hypotensive Drugs.*—In Prof. F. H. Smirk's article last week (p. 695) fig. 4 was intended to show that the 8% M. & B. 1863 in 20% dextran solution with 1/2000 ephedrine prolonged the hypotension as compared with the 5% solution of M. & B. 1863 alone. The lettering on the two arrows at the top of the figure should be interchanged.

Streptomycin—P.A.S. Hypersensitivity.—The article by Dr. Kenneth Marsh in our issue of Sept. 27 (p. 606) contained a report of a sternal marrow biopsy; this report was by Dr. A. P. Peeney.

Progress in Clinical Medicine.—The price of the second edition of this book by Dr. Raymond Daley and Dr. Henry Miller, which was given incorrectly in our review (Oct. 11, p. 716), is 30*s*.

Diary of the Week

OCT. 19 TO 25

Monday, 20th

ROYAL COLLEGE OF SURGEONS, *Lincoln's Inn Fields, W.C.2*
3.45 P.M. Mr. P. H. Mitchiner: The Breast.

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Dr. L. I. Woolf: Inborn Errors of Metabolism in Animal and Child.

HUNTERIAN SOCIETY
7 P.M. (Talbot Restaurant, 64, London Wall, E.C.2.) Dr. Basil Parsons-Smith: Cardiology—Old and New. (Presidential address.)

Tuesday, 21st

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. L. W. Proger: Blood Vascular Diseases.
5 P.M. Mr. K. W. Starr: Acute Postoperative Dilatation of Stomach. (Hunterian lecture.)

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene, Keppel Street, W.C.1.) *Prof. C. G. Douglas*, F.R.S.: *Control of Respiration.*

INSTITUTE OF DERMATOLOGY, *St. John's Hospital, Lisle Street, W.C.2*
5.30 P.M. Dr. J. P. O'Brien: Prickly Heat and Allied Disturbances *of Sweat Secretion.*

WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck Street, W.1
5.30 P.M. Dr. Colin Edwards: Neurological demonstration.

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mrs. Margaret Pyke, Dr. H. A. Davidson: Family Planning.

SOCIETY FOR THE STUDY OF ADDICTION
8 P.M. (11, Chandos Street, W.1.) Dr. John Yerbury Dent: Possibilities of Apomorphine in Treatment of Drug Addiction.

SOUTH WEST LONDON MEDICAL SOCIETY
8.30 P.M. (Bolingbroke Hospital, Wandsworth Common.) Sir Arthur Porritt: Sport Injuries.

Wednesday, 22nd

INSTITUTE OF DERMATOLOGY
5.30 P.M. [illegible] Technique.

INSTITUTE [illegible]
3 P.M. [illegible] Road, W.12.) Prof. [illegible] In [illegible] ollowing Ultra-radical Surgery.

MIDLAND MEDICAL SOCIETY
8.15 P.M. Sir Allen Dal [illegible] Today.

SCOTTISH SOCIETY OF THE [illegible]
4 P.M. (Royal College o [illegible] Symposium on Plague.

Thursday, 23rd

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. H. F. Lunn: High Ligation of Neck of Sac in Inguinal Hernia. (Arris and Gale lecture.)

UNIVERSITY COLLEGE
5.30 P.M. Sir Geoffre [illegible] Prodromes to Cortical Localisation. [illegible] re.)

BRITISH POSTGRADUATE [illegible]
5.30 P.M. Prof. D. Keilin, F.R.S.: Metal Catalysis and Intracellular Respiration.

ROYAL SOCIETY OF MEDICINE
8 P.M. *Section of Urology.* Mr. J. G. Yates Bell: Hydronephrosis. (Presidential address.)

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, S.W.1
5 P.M. Dr. J. Hamilton Paterson: Neurological lecture-[illegible]

[illegible] IETY
[illegible] of Manchester.) *Section of Anæsthetics.* [illegible]: *Recollections not Confessions.* (Presidential address.)

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. W. S. Shearer: *Radiographic Features of General* [illegible] the Skeleton.

[illegible] DREWS
[illegible] *hool, Small's Wynd,* Dundee.) Prof. J. C. [illegible] of Growth of Bones.

Friday, 24th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. P. W. Brand: Reconstruction of the Hand in Leprosy. (Hunterian lecture.)

ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of Obstetrics and Gynæcology.* Mr. A. C. Palmer: Changing Practice in Obstetrics and Gynæcology. (Presidential address.)

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. W. Barber: Clinical demonstration.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION
8.30 P.M. (Royal Free Hospital School of Medicine, 8, Hunter Street, W.C.1.) Mr. Justice McNair: Organisation of the Law.

Saturday, 25th

CAMBRIDGE UNIVERSITY
10.30 A.M. (Addenbrooke's *Hospital.*) Postgraduate symposium on nervous diseases.

HEBERDEN SOCIETY
10 A.M. (B.M.A. House, *Tavistock Square,* W.C.1.) Lord Horder: Rheumatism—a National Problem. (Heberden oration.)

THE CAUSE AND TREATMENT OF LEG ULCERS *

S. T. ANNING
M.A., M.D. Camb., M.R.C.P.
ASSISTANT PHYSICIAN, DERMATOLOGICAL DEPARTMENT, THE GENERAL INFIRMARY AT LEEDS

LEG ulcers are common in this country, especially among women, and cause much pain and grave disability. Although sometimes the result of chilblains, tuberculosis, syphilis, or other conditions, they are more often caused by disease of the circulation, and it is this kind that I shall consider here.

My review will incorporate the results of personal observation of 715 patients (496 women and 219 men) suffering from the kind of ulcer which usually affects the lower third of the leg and is variously known as varicose, stasis, or gravitational.

The common leg ulcer is associated with chronic œdema, induration, sclerosis, and pigmentation; loss of hair and eczema of the leg are also often present. Varicose veins may or may not be found. These signs are evidence of a defective venous return of blood from the leg, and this has long been recognised.

HISTORICAL SURVEY

Hippocrates noted the association of varicose veins and leg ulcers (Adams 1849); but, until Harvey (1628) demonstrated the circulation of the blood, and for some time after, it was thought that ulcers were caused by humours. Derived probably from the humoral theory was the idea of menstrual ulcers: according to Ambroise Paré in 1579 (Johnson 1678), menstrual blood collected in the legs during pregnancy and became stagnant, causing ulceration; and even in the first half of last century Sir Astley Cooper (1837) and Critchett (1848) wrote of menstrual ulcers related to amenorrhœa from any cause. The idea that ulcers are caused by stagnation of blood in the leg seems to have persisted in the concept of venous stasis.

However, Harvey's discovery did have some effect on the views held about leg ulcers. Wiseman in 1676 wrote about venous thrombosis, the dilatation of veins, and the results of these conditions on the valves; he seems to have been the first to consider that ulcers might be the direct result of a circulatory defect.

Most of the 18th-century writers on the subject, such as Underwood (1783), Bell (1779), Baynton (1799), and Whately (1799), do not refer to varicose veins as a cause. But a new idea was growing: "the Indisposition of these Sores is in some measure owing to the Gravitation of the Humours downwards" wrote Sharp (1758): and Baynton (1799) declared that the disease arises "from the unfavourable situation of the parts which are placed at a remote distance in the human machine from the fountains of life and heat, and are obliged to return the venous blood and lymph to the heart under some peculiarly unfavourable and disadvantageous circumstances."

In the view of these 18th-century writers a leg ulcer followed a wound which failed to heal because of the erect posture and the resultant œdema. Everard Home (1801) believed that an ulcer was more difficult to heal if there were varicose veins, and Hodgson (1815) wrote of ulcers "which are generally situated near the ankle and are remarkably intractable. They appear to depend upon the varicose condition of the veins, for when the latter is relieved, the ulcers are as readily cured as ulcers in general." Other writers of last century (Brodie 1846, Chapman 1853, 1864, Astley Cooper 1837, Hunt 1859, Hilton 1861, Critchett 1848, and several more) placed the emphasis on varicose veins as the important cause, and the term "varicose ulcer," scarcely used since Wiseman (1676), became established.

Gay and Spender, two authors of outstanding books, both published in 1868, went much further: they thought that venous thrombosis also played a part. Indeed, Gay denied the validity of the doctrine of the varicose ulcer and believed, like Chapman (1853), that the term should be discarded.

Although Verneuil (1855a and b), in France, had made careful observations and dissections, Gay's work seems to have been the first scientific investigation of these conditions in this country. He pointed out, as did Nunn (1852), that severe varicosity may exist without ulceration—a useful observation neglected until recently (Lockhart-Mummery and Smitham 1951). He further noted that with superficial varicosity there may be other serious lesions affecting both arteries and veins, deep and superficial, which cannot be ignored, and he concluded that

> "ulceration is not a direct consequence of varicosity, but of other conditions of the venous system with which varicosity is not unfrequently a complication, but without which neither one of the allied skin affections [induration and bronzing] is met with, conditions which involve obstruction of the trunk veins, deep and superficial, either from impediments on the venous side, or incompetency on the arterial, or from both causes combined."

He introduced the term "venous ulcer" and was the first to describe the "arterial ulcer" caused by obliterative disease of the walls of arteries.

Since the time of Gay there has been little advance in our knowledge of these conditions. Many surgeons have remained obsessed with the primary ætiological importance of varicose veins and have directed their attention to injecting, tying, removing, or scarifying them. From the modern surgical textbook we learn little about the cause of ulcers, though the authors often write at length about the treatment of varicose veins. Dickson Wright (1930) did a great service when he redirected our attention to the essential problem, that of hydraulics. Bauer (1942, 1948, 1950a and b), Birger (1947), Haxthausen (1932, 1937), and other Scandinavians have done valuable work on the ætiology of these ulcers, and many American investigators have added to our knowledge of venous thrombosis and venous pressure.

What then is the present position?

NORMAL BLOOD-FLOW IN LOWER LIMB

The adoption of the upright posture was a great evolutionary advance, but man has had to pay dearly for the privilege of being two-legged. To return the blood from the lower part of the legs to the heart requires it to be raised about twice the height formerly necessary. How is this return accomplished?

> "In some parts of the body, the force of gravitation returns the blood to the heart; and it might seem, that elsewhere, as in the legs, the downward pressure of an arterial column serves to weigh against the inert column in the corresponding veins."

Thus wrote King (1837), and this conception of the hydrostatics of the lower limb is similar to that of Bauer (1950a). The vascular system of the lower limb, Bauer says, may be thought of as part of a large U-tube: if blood is introduced into one side of this U-tube, as happens each time the heart pumps blood into the aorta, an equal amount should flow out of the other end, from the vena cava into the right side of the heart, irrespective of the position of the body. Unfortunately for this analogy, however, the human U-tube does not have rigid or impermeable walls of glass or metal, and there

---

* An address delivered before the Leeds and West Riding Medico-Chirurgical Society, on March 22, 1952.

are loops across the tube joining the two sides. If the capillary resistance is increased, or if there is any obstruction in the arterial or venous part of the most distal loop of the hypothetical U-tube—i.e., that in the lower limb—the flow there may be greatly reduced, though increased in more proximal loops. It is true that the venous pressure in the foot, when the person is standing at attention, is about equal to the weight of a column of blood extending from the point of measurement to the heart, with the addition of the capillary pressure present in the prone position which constitutes the vis a tergo. But many factors affect the venous pressure, as is shown in fig. 1, adapted from Landis and Hortenstine (1950).

The essential point is that, to maintain a satisfactory return of blood from the lower part of the legs in the erect posture, relay pumping is required to force the blood up to the heart. This is done effectively by the squeezing action of the calf muscles, together with the valves in the veins, especially in the deep veins of the calves and thighs, which prevent a reflux down the legs when the muscles relax.

Harvey (1628) described how the blood "is squeez'd out of the capillar veins into the little branches, and from thence into the greater, by the motion of the members and muscles." This was appreciated by Lower (1669), who wrote: "The blood is only driven upwards from the lowest part of the body with difficulty through the impulse of the arterial blood, and at times by the contraction of the muscles in exercise." Wiseman (1676) described the pumping action of the leg mucles aided by the venous valves, and King (1837) recognised its importance in driving the venous blood towards the heart; but until recently it has attracted little interest.

It was demonstrated by Carrier and Rehberg (1923) that even slight involuntary movements reduced the venous pressure in the dependent leg, and Warren et al. (1949) showed that, on walking, the pressure in the saphenous veins of normal people falls considerably. Other workers have found a similar fall of pressure in the leg (e.g., Smirk 1936, Pollack and Wood 1949, Hojensgard and Stürup 1949). It has been confirmed by Walker (1950), who found that the venous pressure in the foot in normal erect people standing still is 70–100 mm. Hg (100–140 cm. water), depending solely on the person's height, but falls to 0–30 mm. Hg (0–40 cm. water) on exercising the legs.

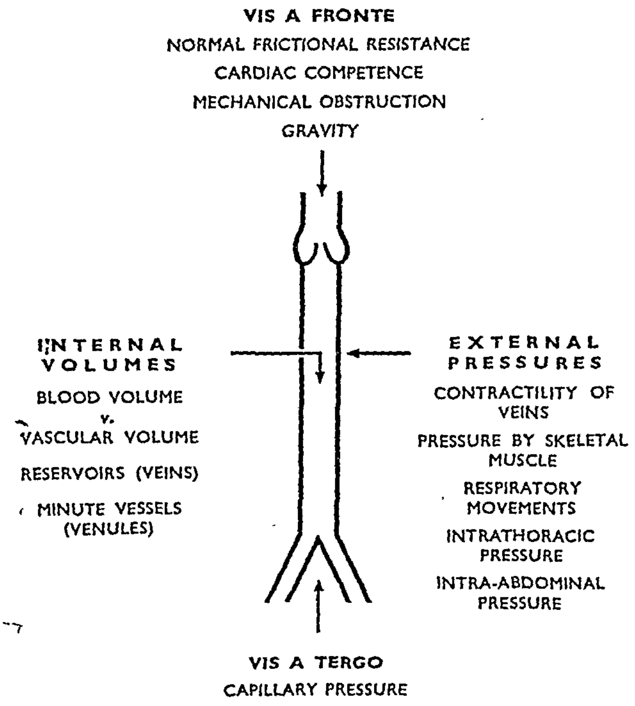

Fig. 1—Factors concerned in maintenance of venous blood-pressure (after Landis and Hortenstine 1950).

So effective is the leg muscle pump that in normal people there is no continued rise in venous pressure unless they stand for a long time in one position.

Some assistance to the return of blood to the heart may also be given, during inspiration, by the negative pressure in the thorax and the compression of the iliac veins by the increased pressure in the lower abdomen (Warwick 1931; cf. Franklin 1937).

CAUSES OF FAILURE OF LEG MUSCLE PUMP

Venous Thrombosis

Thrombosis may start in the veins of the foot or of the calf and spread upwards into the deep veins of the thigh. Some workers believe that it is useful to distinguish between phlebothrombosis, in which the thrombus is readily detached causing embolism, and thrombophlebitis with a primary inflammatory lesion in the vein (Ochsner 1946). Venous thrombosis of either type is more likely to develop in people with varicose veins or who have inherited a tendency to varicose veins (Anning 1950); in those lying at rest for some days, during which the blood-flow in the leg veins may be slowed; in conditions where the wall of the vein is injured; and where there is local infection. Thus we find thrombosis after childbirth (especially with pelvic infection), after certain illnesses—e.g., typhoid fever and pneumonia—after operations (particularly in the lower abdomen and pelvis), and after injury. The wall of a vein may be damaged by comparatively slight injury to the leg or by fracture, by operations on the leg, or by the injection of sclerosing solutions, which may pass from the superficial to the deep veins. Occasionally thrombosis occurs for no apparent reason (DeCamp et al. 1952).

According to Bauer (1942), a much greater quantity of blood normally passes through the deep veins than through the superficial. Because of the obstruction caused by thrombosis in the deep veins, a fresh route must be found for blood passing from the foot and leg to the abdominal veins. An enormously increased amount therefore flows through the superficial veins, which become dilated and may later become varicose. Varicosity following thrombosis is usefully described as secondary, and Curtis and Helms (1947) regard it as the commonest type.

Incompetence of Deep Valves

The valves of the deep veins may be absent, dilated, or destroyed. Congenital absence of valves in the deep veins has been described (Eger and Casper 1943, Curtis and Helms 1947), and the number of valves proximal to the saphenofemoral junction is often inconstant in adults.

Incompetence of the valves may result from dilatation of the vein. The tendency to varicosity may be inherited as a dominant character (Anning 1950), and in affected families dilatation of leg veins or hæmorrhoidal veins or veins elsewhere may appear after various periods of increased intravenous pressure, as produced in the leg veins by raised abdominal pressure from straining or coughing or by standing still at work—e.g., "standing too much before kings" (Marianus Sanctus Barolitanus 1555). Pregnancy is an important cause of this primary type of venous dilatation. These causes of varicosity of superficial veins are well recognised, but it is not always appreciated that the deep veins may also be dilated, although this was described by Verneuil (1855a and b) and Gay (1868), and has lately been demonstrated phlebographically by Moore (1951).

Destruction of the venous valves follows thrombosis, and recanalisation of the vein produces an irregular valveless tube (Homans 1917, Edwards and Edwards 1937, Bauer 1948).

Lack of Muscular Contraction

With long standing in one position, or with arthritis affecting the knees or ankles, contraction of the calf muscles may be so weak or intermittent that the leg muscle pump may fail.

RESULTS OF INEFFICIENCY OF LEG MUSCLE PUMP

If the leg muscle pump is inefficient and the venous return from the lower limb is consequently defective, the result will be œdema of the limb, and eventually pigmentation, induration, and ulceration. Where there is varicosity of the leg but the valves in communicating and deep veins are efficient, œdema does not develop more rapidly than in a normal leg, but the rate is significantly increased when these valves are incompetent (Holling et al. 1938).

It is worth consideration that in cardiac œdema, renal œdema, and œdema caused by lymphatic obstruction the complications just mentioned do not arise unless venous thrombosis or one of the other causes of venous insufficiency is also present.

In cardiac œdema the limb is pale and soft and pits readily. Acupuncture does not cause ulceration as it would certainly do in a leg with chronic venous insufficiency. The same remarks are true of chronic œdema from renal disease, the nephrotic syndrome. Furthermore, in the firm pale non-pitting œdema of the leg with lymphatic obstruction ulceration does not occur.

The reason for this difference between chronic venous insufficiency and these other conditions seems to lie in the venous and capillary pressures. In cardiac œdema the venous pressure is raised but the right auricular pressure is only, at most, 30 cm. water above the normal, and the valves in the deep veins protect the lower limbs against this rise except during systole of the leg muscle pump. Cardiac œdema is not caused by the rise in venous pressure but by reduced renal blood-flow with retention of salt and water (Brod and Fejfar 1950).

In chronic renal disease with œdema the venous and capillary pressures are not raised and œdema results from the reduction in the osmotic pressure of the blood owing to loss of serum-protein.

In lymphatic œdema too there is no rise in venous or capillary pressure. Fluid is retained in the tissues by lymphatic blockage and by the high protein content of the tissue fluid.

In chronic venous insufficiency, on the other hand, the venous, and therefore the capillary, pressure is greatly increased. During exercise the venous pressure in the foot is 50–110 mm. Hg (70–150 cm. water) instead of the normal 0–30 mm. Hg (0–40 cm. water) (Walker 1950). As a result there is considerable capillary damage with loss of fluid containing protein and red blood-cells (Massell and Kraus 1950). This fluid becomes organised with firm induration of the limb. Because of the capillary damage metabolic exchange is impaired and capillary thrombosis may take place, followed by necrosis. This, or failure of the tissues to heal after injury, produces ulceration, which is more common where the tissues are indurated. The area of induration may be localised, and through it a dilated superficial vein, left as a soft channel, may pass. Such an area may result from low-grade inflammation of the subcutaneous tissue, probably related to thrombosis of small superficial veins. When chronic venous insufficiency has been present untreated for a long time, lymphatic obstruction is probably also present.

The results of failure of the leg muscle pump are similar whatever the cause. Ulceration and other changes following venous thrombosis in the lower limb cannot be distinguished clinically from those caused by incompetent valves in the deep veins, whatever the reason. This view is also held by Lockhart-Mummery and Smitham (1951).

It will be noted that no mention has been made of venous stasis. Blalock (1929) found that, in patients with varicose veins of only one of the lower limbs, the oxygen content of blood from the femoral or from the saphenous veins was higher on the affected side. Moreover Holling et al. (1938) found no difference between the oxygen tension in the blood from normal leg veins, simple varicose veins, and varicose veins with ulceration. However, if an arteriovenous shunt is present in the leg after venous thrombosis, as demonstrated arteriographically by Brewer (1950), estimations of the oxygen content of venous blood from the leg may be misleading. Even so, Haxthausen's investigations on the temperature of ulcerated legs (1932) and on the circulation of dyes injected into varicose veins (1937) suggest that venous stasis is absent or unimportant—a conclusion also reached by Abramson and Fierst (1942) using plethysmographic methods.

Probably high venous pressure and the resulting capillary changes, and not venous stasis, are the essential causes of these leg ulcers. Although the rate of blood-flow through the lower limb may be reduced by failure of the leg muscle pump, and although the flow through dilated veins may be slow, tissue metabolism can only be affected by the capillary circulation and not by venous stasis, even were it present.

To sum up, chronic venous insufficiency may be brought about by thrombosis in the deep veins, with or without recanalisation; by primary varicosity of the deep veins usually accompanied by incompetent perforating veins and superficial varicose veins, causing true "varicose ulcers"; and by lack of muscular contraction, as with arthritis of the knees or ankles, or a job which involves standing. Often there is a combination of these causes, and in addition there may be arterial disease affecting the capillary blood-flow.

ARTERIAL DISEASE

Gay (1868) and Heller (1943) regarded arterial disease as an important cause of some chronic leg ulcers. Ulceration from arteriolar occlusion with hypertension was described by Martorell (1945) and Hines and Farber (1946). Arteriosclerosis obliterans (affecting larger vessels), with or without hypertension, may also cause ulceration (Shapiro and Nomland 1950), and it was this condition that Gay called "arterial ulcer."

Martorell (1945, 1950, 1951) has described "hypertensive ulcers" on the supramalleolar region, usually on the anterolateral aspect at about the junction of the middle and lower thirds of the leg. Ulceration is often bilateral and symmetrical. There is much pain which is not relieved by rest in bed. Œdema and other signs of disturbance of the venous circulation are absent. As there is usually no occlusion of the main arteries, pulsation may be felt in the lower limb. Histologically, obliterative changes similar to those found elsewhere in hypertensive people are found in the small arterioles of the legs. These ulcers are uncommon but are found more often in women than in men. Improvement is said to follow sympathectomy.

CLINICAL OBSERVATIONS

Fig. 2 shows the main cause of ulceration in 715 patients examined personally. In 15 patients venous thrombosis developed on two occasions from different causes. Hence, though 569 patients (79·6%) had post-thrombotic ulcers, thrombosis is shown in the figure of 584 ulcers. The large number of patients who had had either post-partum thrombosis (28·8% of the women) or traumatic thrombosis will be noted. As regards the non-thrombotic ulcers, 51 (7·1%) patients had true varicose ulcers, 8

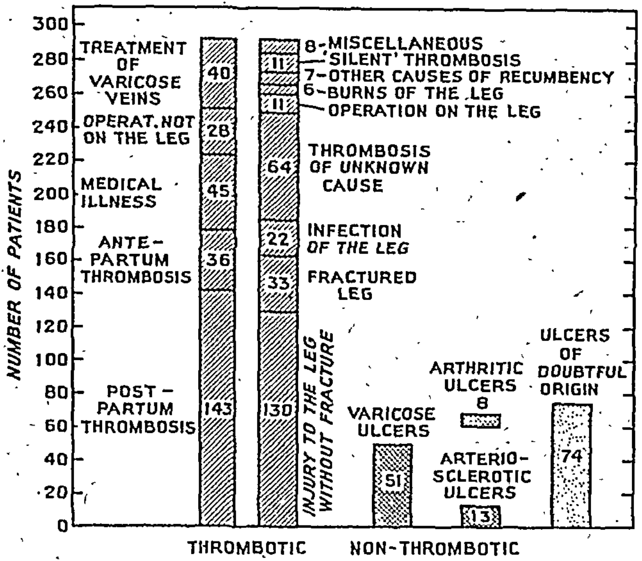

Fig. 2—Causes of leg ulcers in 715 patients.

(1·1%) had ulcers from arthritis alone, and in 74 (10·4%) the cause of venous insufficiency was doubtful. There were 13 patients (1·8%), 11 women and 2 men, with ulcers of the arterial type and hypertension: 3 of them had diabetes mellitus; 9 showed signs of arteriosclerosis obliterans, and 4 of these had calcification of large arteries shown radiologically; and 4 patients, all women, had gross hypertension and ulcers of the type described by Martorell (1945). In all 13 of these patients the feet were very cold.

HYPERTENSION

Besides the group of patients with arterial or hypertensive ulcers, a large proportion of those with post-thrombotic and varicose ulcers had hypertension (figs. 3 and 4). Comparison of 172 women patients with a large unselected group of American women showed that the proportion of ulcer patients with hypertension is significantly higher than in the control group (Anning 1949). Unfortunately no standard figures for blood-pressure readings of the English population seem to exist.

The relation between hypertension and ulceration from defective venous circulation is obscure. Kulwin and Hines (1950a and b) showed that, in patients with chronic venous insufficiency, there were hypertrophic and degenerative changes in the arterioles and venules of the lower limbs—sometimes in the absence of hypertension and in skin that appeared normal. These changes are similar to those reported by Gonin (1950) in patches of "white atrophy" of skin near the ankles, which patches often break down to form small painful ulcers resembling, apparently, those described by Corlette (1927). "White atrophy" usually appears in association with chronic venous insufficiency; it has been described by Critchett (1848) and Milian (1936).

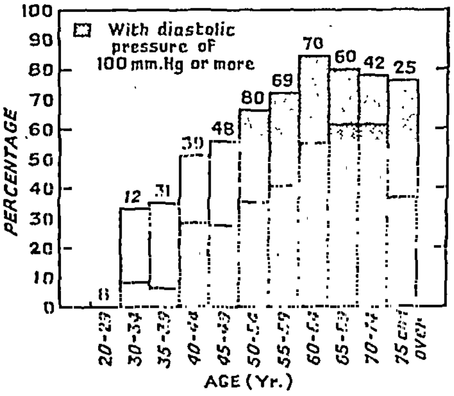

Fig. 3—Incidence of hypertension (diastolic blood-pressure 90 mm. Hg or more) in 484 women with leg ulcers. Numerals above histograms denote numbers of patients.

The cause of these arteriolar changes in the lower limbs of patients with chronic venous insufficiency is not known. It seems unlikely that they are merely secondary to arterial hypertension, because the changes were present in some of the patients of Kulwin and Hines (1950a and b) in the absence of raised blood-pressure. Is it possible that they are secondary to the rise in venous and capillary pressure? Furthermore, is it possible that the rise in blood-pressure found in so many patients with post-thrombotic and varicose ulcers may be secondary to the arteriolar changes in the lower limbs and to the resulting rise in peripheral resistance? Were this so, a relation might be expected between the duration of the venous defect (accurately determined when there is a history of venous thrombosis) and the blood-pressure. In the present series no such relation was found.

It is, of course, possible that hypertension and the presence of deep varicose veins or the predisposition to venous thrombosis might occur in the same families, but this seems unlikely. In the present series there is no relationship between hypertension and body-weight. Many of the lighter patients had a raised blood-pressure.

Perhaps hypertension with arteriolar changes is a coincidental finding which, in patients with a defective venous return from the lower limb, predisposes to ulceration.

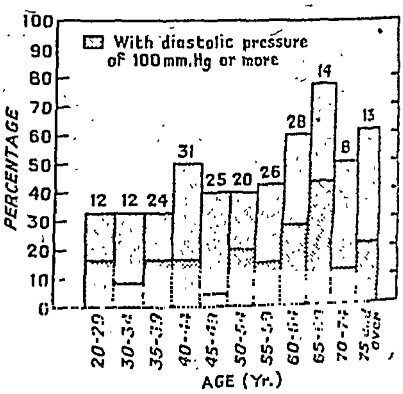

Fig. 4—Incidence of hypertension (diastolic blood-pressure 90 mm. Hg or more) in 213 men with leg ulcers. Numerals above histograms denote numbers of patients.

OBESITY

Of the 715 patients 684 (472 women and 212 men) were weighed. Though a small proportion were extremely heavy, 67% of the women and 64% of the men weighed 79 kg. (174 lb.) or less (fig. 5). Obesity, if present, seems to play a part in this condition but not a primary one, and weight reduction aids the healing of ulcers in heavy people. Thrombosis, according to Barker et al. (1941), occurs twice as often in those who weigh more than 91 kg. (200 lb.).

OCCUPATION

As regards occupation, 309 (62·3%) of the 496 women, being housewives, were on their feet most of the day, and of the remainder 148 (29·8%) stood at work in their employment as shopkeepers, as weavers, or otherwise. Only 24 (1%) of the 219 men had sedentary occupations.

TREATMENT

The prevention of ulceration is worth consideration, and here the prevention of venous thrombosis is clearly of paramount importance. I shall do no more than mention here the value of leg exercises in recumbent patients, especially when the limbs have been compressed from toes to groins (Ochsner 1947), and the postoperative use of anticoagulant substances in small dosage (Allen et al. 1947).

Chapman (1864) noted "the greater risk of Phlegmasia Dolens occurring in women who suffer much from varix during pregnancy." From a study of heredity in these conditions it can be said that where thrombosis is apt

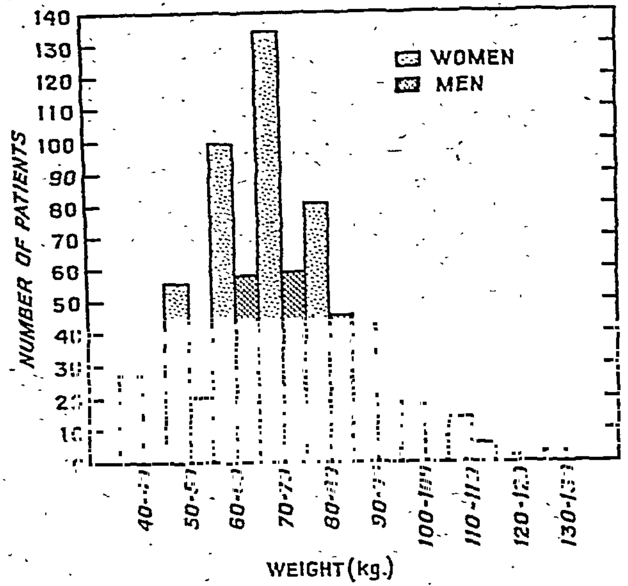

Fig. 5—Weight-distribution of 684 patients (472 women and 212 men) with leg ulcers.

to develop, as in parturient women, patients recumbent for medical or surgical reasons, and those with fractures of, or undergoing operations on, the leg, special efforts should be made to prevent it if there is a family history of varicose veins, thrombosis, or leg ulcers (Anning 1950).

When thrombosis has occurred, early treatment with anticoagulants is useful, and firm support for the limb will prevent the appearance of secondary varicose veins and control the œdema. When the acute phase has passed, massage by Bisgaard's (1948) method, together with continued elastic support, will prevent induration of the leg and subsequent ulceration.

The prevention of true varicose ulcers is a simpler matter. When there are early signs of chronic venous insufficiency adequate elastic support is sufficient. The value of the surgical treatment of superficial varices is doubtful; sometimes it precipitates ulceration.

Rest

Once ulceration has taken place, early treatment is important. The longer an ulcer remains untreated the more difficult is its cure. Except for ulcers of many years' duration with much induration, which may require rest in bed, it is only necessary to abolish the œdema and the ulcer will heal.

The value of rest has long been recognised. It was described by Bell (1779) as a material part of the cure, and by Cooper (1837) as indispensable, and Sharp (1758) emphasised the importance of rest in a horizontal position. However, a new approach was introduced by Underwood. In 1783 he published a treatise "proving that a Perfect Cure may generally be effected more certainly, without Rest and Confinement, than by the Strict Regimen in Common Use."

Compression

The cure of ulceration in a walking patient requires compression of the limb to abolish the œdema or to prevent its return. As Bisgaard (1948) pointed out, the massaging effect of the muscular contractions of a leg compressed by elastic bandages helps to remove the œdema, and the patient may be encouraged to walk.

The use of plaster bandages for leg ulcers was advised by Marianus Sanctus Barolitanus (1555). Paré (Johnson 1678) and de Marque (1618) recommended compressive bandages, but treatment by firm support does not seem to have been widely used until Wiseman (1676) introduced the laced leather stocking. Continental surgeons soon adopted this kind of stocking, one of which is illustrated by Dionis (1708). Wiseman also mentioned bandaging, but this does not seem to have come into general use for some time—certainly not by the time of Else (1771), who found that a tight roller bandage applied from the toes to the knees was much better than a laced stocking.

Underwood (1783) wrote in great detail of the treatment by bandaging and used "Welch flannel" because it was elastic. He considered that "the application of a bandage is no contemptible branch of our profession." The same view was taken by Hunt (1859), who said that the treatment of leg ulcers was so notoriously unsuccessful "mainly because the application of a bandage is looked upon as an easy and simple operation which may safely be entrusted to the nurse or the patient." He added that the bandage must be applied "in such a manner that every portion of the limb, from the toes to the knees (including especially the hollow between the heel and the inner and outer malleolus) shall receive equal and abiding support. If it be at all tighter round the leg, for instance, than round the foot, the foot and ankle will become swollen and œdematous." Spender (1868) also gave detailed instructions about bandaging.

The importance of good support in the treatment of leg ulcers must be emphasised whether or not surgery is used in addition. Firm elastic support is beneficial because it relieves the œdema, assists the pumping and massaging effects of muscular contraction, and compresses dilated veins.

Various types of support have been devised since Wiseman's leather stocking and Underwood's flannel roller. Baynton (1799) reintroduced the plaster bandage, and Dickson Wright (1930) demonstrated the value of the elastic plaster bandage. Most leg ulcers can be cured in a few months with such bandages, and preliminary painting of the leg with 1% aqueous solution of gentian violet greatly reduces the risk of 'Elastoplast' irritation. An elastic webbing bandage worn over stockinette provides excellent support, preferably when it stretches longitudinally only: bandages which stretch in two directions tend to become progressively narrower. Scott and Radakovich (1949) have introduced a stocking which allows controlled pneumatic pressure to be applied to the œdematous leg. Whatever method of compression is adopted, the patient should be encouraged to walk.

The Unna's-paste bandage or its convenient successor, the 'Viscopaste' bandage, is useful to support the limb after œdema has been abolished by other means. These bandages have no elasticity; but, if compression is required, elastoplast bandages may be applied over them.

The advantages to be derived from elastic support combined with deep massage were demonstrated by Bisgaard (1948). Deep massage is given to the sole and the hollows by the malleoli with the leg raised. Padding is next placed in the hollows, and the leg, from the toes to the knee, is covered with wadding, over which a firm elastic webbing bandage is wound. The patient is encouraged to walk. I have found Bisgaard's treatment valuable in the reduction of œdema and induration of the leg and in the healing of ulcers. I cannot compare the results of this method with those of other types of treatment, because I have had to limit its use to patients with severe induration and œdema or with intractable ulcers. However, several patients whose ulcers had resisted conventional treatment, surgical and other, were cured by Bisgaard's method. Patients treated in this way seem less prone to relapse.

Local Treatment

No mention has been made of infection of ulcers, for it plays no primary part in their ætiology. Inevitably an ulcer becomes secondarily infected with various organisms commonly present on the skin, but this rarely affects healing when treatment is based on the principles outlined above. If attention is directed to the circulation of the limb as a whole, the base of the ulcer and its flora may usually be ignored. Occasionally ulcers are seen which rapidly increase and become offensive and surrounded by erythema. On bacteriological examination *Pseudomonas pyocyanea*, proteus, or a virulent streptococcus may be found. Local treatment with a suitable antibiotic may be required for a few days. Penicillin and the sulphonamides are best avoided because the risk of sensitisation is great. Lassar's paste containing sodium bicarbonate 25% is effective in cleaning an offensive ulcer. Recently the unsaturated fatty acids have been advocated as a local application for ulcers, but they appear to have no beneficent quality other than as a soothing dressing.

Surgical Treatment

I do not intend to be so presumptuous as to discuss the surgical treatment of leg ulcers, but merely to make a few rather diffident remarks. The danger of thrombosis of deep veins after the injection of varicose veins with a sclerosing solution has been pointed out by several surgeons (Boyd and Robertson 1947, Kinmonth and Robertson 1949). The risk can be reduced by certain precautions but cannot be ignored. In the present series 48 patients had deep thrombosis after such injections, and in 32 (4·5%) the thrombosis was the direct cause of ulceration. Moreover the injection of secondary varicose veins—i.e., veins appearing after thrombophlebitis of deep veins—further embarrasses the venous return from the leg, even though another deep thrombosis is avoided.

About the results of ligation of the saphenous veins little can be said here. Such treatment may benefit temporarily a few patients with true varicose ulcers, but the seat of the trouble is in the deep and communicating veins, and relapse is common. After saphenous ligation in 48 patients ulcers became worse or appeared later, and in 8 other patients ligation was the precipitating cause of ulceration.

Ligation of the popliteal vein, introduced by Bauer (1948), seems to be successful in his hands in curing ulcers and relieving the bursting pain in the legs. On radiographic evidence, he thinks that reflux of blood down the femoral vein is prevented, and that the blood is driven by contraction of the calf muscles into the muscle veins of the thigh (Bauer 1950b). The patients are advised to wear elastic stockings after the operation. The results of this operation in the hands of British surgeons do not seem to have been reported, but de Takats and Graupner (1951) feel that ligation of the popliteal vein does more harm than good.

On theoretical grounds it seems that the rational surgical treatment would be the introduction, if thrombosis could be avoided, of an artificial valve (of plastic or metal) in the iliofemoral veins.

Sympathectomy seems to be indicated when arterial disease is present, if lowering of sympathetic tone is shown beforehand to be followed by vasodilatation. Ochsner and DeBakey (1949) believe that vasospasm is a common sequel of deep thrombosis, and that sympathectomy causes the œdema to disappear.

Excision of the ulcerated area, followed by grafting, is occasionally indicated where much sclerosis is present and the ulcer is bound down to deeper structures. However, unless combined with measures to control œdema, it is doomed to failure.

AFTERCARE

It is too often forgotten that the medical care of the patient with a leg ulcer should not cease with its cure. Unless aftercare is adequate, relapse is probable. Else (1771) recommended that "when the patients are well" they should "keep the leg constantly rolled tight in the day-time." This is good advice; for, unless return of the œdema is prevented by elastic stockings or firm bandages, ulceration will reappear.

To ensure that the patients are wearing adequate support for the legs, it has been found best to see them every three or four months after cure, so that fresh bandages or stockings can be ordered as required, and satisfactory support permanently maintained. As yet no surgical treatment can offer an alternative.

SUMMARY

The growth of knowledge of the ætiology of leg ulcers is reviewed historically.

The importance of an increase in venous and capillary pressure in the lower part of the leg is emphasised, the essential defect being shown to lie in the valves of the deep veins of the lower limb.

Of 715 patients the cause of such trouble was venous thrombosis in 80%, and varicosity of deep veins in 7%.

Ulcers due to hypertension are described, and the problem of arterial and arteriolar disease in relation to leg ulcers is discussed.

In addition to methods of prevention, treatment by rest, elastic support, massage, and surgery is considered.

Aftercare is necessary to prevent relapse.

It is a pleasure to acknowledge the kindness of Dr. John T. Ingram, Dr. F. F. Hellier, and other colleagues and practitioners who have referred patients to me. The help and skill of Sister Irene Gray and Sister Blanche Simpson have been invaluable in the treatment of these patients.

VAGOTOMY IN THE TREATMENT OF PEPTIC ULCERATION

REVIEW OF 1524 CASES

A. V. POLLOCK
M.B. Cape Town, F.R.C.S.

SURGICAL TUTOR, UNIVERSITY OF LEEDS; LATE RESIDENT ASSISTANT SURGEON, WEST LONDON HOSPITAL

FASHIONS in the treatment of chronic peptic ulceration come and go, and the surgical problem remains unsolved. Virchow in 1855 stated that ulcers are caused by peptic digestion of devitalised tissue, and since that time speculation and experiments have centred on the causes preventing healing of these erosions. On the one hand, the lack of resistance of the stomach and duodenal lining is nearly as much a mystery today as it was fifty years ago. On the other hand, excessive secretion of hydrochloric acid has been found to be a factor more amenable to control than any other, and there is considerable clinical and experimental evidence to show that modification of the gastric acidity will favour healing of an ulcer.

The secretion of hydrochloric acid has long been attributed to two separate mechanisms: firstly, gastrin, liberated by food stimulation of the pyloric antrum circulates in the blood-stream and specifically releases hydrochloric acid from eosinophil cells in the stomach (Jory and Whitlow, cited by Wright 1940); secondly, stimulation of the vagus increases the secretion of acid. The central connections of the vagus nerves with the hypothalamus have been adduced as evidence that the emotional flow of acid is governed through these nerves. Much recent work (Wolf and Wolff 1943) has been directed towards correlating peptic ulceration with long-standing conditions of emotional strain. The rationale of resection of the vagus in the treatment of ulceration is obvious (Beattie 1949).

The operation was first used to any extent in Germany from 1914 to 1924 (Alvarez 1948). It fell into disuse and was never done again in the English-speaking countries until Dragstedt and Owens (1943) reintroduced it. The simplicity of the operation, the absence of mutilation, and its theoretical background formed a strong appeal, and many surgeons in the U.S.A. soon adopted it (Moore 1948, Grimson et al. 1949, Walters 1949).

Vagotomy was first adopted in this country in 1945 by Orr and Johnson (1949), and surgeons in many centres were soon using the operation. It was discovered that section of the vagus, if complete or nearly complete, produced an undesirable gastric atony with retention; and various drainage procedures were combined with vagotomy to overcome this effect. These varied from pyloroplasty and pylorectomy (Beattie 1950) to gastrojejunostomy and limited gastrectomy (Orr and Johnson 1949).

The present series comprises 1524 patients with peptic ulcer of the duodenum (1314 cases), stomach (127 cases), jejunum (82 cases), or œsophagus (1 case).

METHOD OF SELECTION OF CASES

After preliminary discussions and a pilot survey at the West London Hospital, leading surgeons in all the main centres in England, Scotland, and Wales were circularised. Where a reply indicated a series of more than 20 cases, that surgeon was visited and his coöperation sought. In no case was this refused. His series was then collected—usually by referring to the operation register in his hospital, but occasionally, when he had notes of all cases recorded at the time of the operation, by referring solely to this record. All the series were consecutive and included every case operated on up to the end of April, 1950. Cases were collected from Birmingham, Bridge of Earn, Bristol, Edinburgh, Leeds, Leicester, London, Manchester, Newcastle, and York.

745 patients (49%) have been interviewed; 632 patients (41·4%) have replied to a questionnaire; 19 patients (1·2%) had died within twenty-eight days of operation; 31 patients (2%) had died later; and 97 patients (6·4%) are untraced. No patient was regarded as untraced until he had failed to reply to three letters or until a letter was returned by the Post Office.

CRITERIA FOR OPERATION

These varied little from surgeon to surgeon and in general were the same as those for gastrectomy. Length of history and relapse after medical treatment were the commonest indications. Thus in the whole series 958 (63%) had an ulcer history of six or more years, and 470 (31%) one longer than ten years. 222 patients (14%) had previously perforated on one or more occasions, 193 (13%) had had one or more major hæmatemeses or melænas, 42 (3%) had both perforated and bled, and 127 (8%) had had a previous gastric operation for their ulcer. In 85 this was a gastrojejunostomy, in 24 a gastrectomy, in 11 a physiological gastrectomy, in 3 excision of an ulcer, in 3 repair of a gastrocolic fistula, and in 1 a pyloroplasty.

Vagotomy the Sole Operative Procedure

736 patients thus treated were studied (table I). 78 patients had died or were untraced, leaving 658 patients followed up from six months to four years. Of the 78 missing patients 10 (1·3%) died in the early postoperative period (1 of these died from hæmorrhage from his ulcer), 18 (2·4%) died later (none from the effects of an ulcer), and 50 (6·8%) were untraced.

40 patients were assessed from six months to a year after operation, 237 from one to two years, 265 from two to three years, and 116 from three to four years after operation. Only 18% were followed up longer than three

years. This detracts from the value of the investigation; nevertheless even within the short space of this follow-up there has been a considerable incidence of failure due to gastric retention and recurrent ulceration.

80 of these operations were done by the transthoracic route. The results were compared from the point of view of recurrence and retention, and differed in no way from those of abdominal vagotomy (except for pain in the thoracotomy incision). The two types are considered together.

FOLLOW-UP FINDINGS

Relief of Pain

In nearly every case this was immediate and complete. The mechanism of this relief is conjectural. It has been supposed (Grimson et al. 1947) that the vagus carries no sensory fibres, and that the relief of pain results from immediate gastric atony. On the other hand, Mr. Beattie tells me that on several occasions he has crushed the anterior vagal trunk under spinal anæsthesia and caused sharp epigastric pain. This contradicts the findings of Foerster (cited by Alvarez 1948), who produced nausea but no pain by such stimulation.

Recurrences of Pain

Many patients complained of occasional or frequent mild or severe abdominal pain. On the basis of relief of this pain by food and similarity to preoperative pain it has been called recurrent ulcer pain or recurrent pain (other causes). 167 patients (25%) have admitted to epigastric pain relieved by food at some time since operation. 240 patients (36%) have complained of other abdominal pain, usually taking the form of "wind," or colic, and sometimes associated with diarrhœa or with a sense of fullness.

Dysphagia

Mild difficulty in swallowing in the early days after vagotomy is very common. It sometimes persists and has necessitated dilatation of the cardia. In only 5 patients has it persisted longer than six months. It was remembered by 198 patients (30%). In the single case of œsophageal-hiatus sliding hernia with peptic ulceration and stricture of the lower œsophagus vagotomy was followed by an exacerbation of pain and dysphagia necessitating resection of the lower œsophagus.

Diarrhœa

This was an extremely common symptom, especially during the first six months after operation. It occurred in a mild form in 353 patients (53%) and in a severe form in 108 patients (16%). In 3 cases it contributed to death in the early postoperative period. Necropsy and bacteriological examination in 1 case threw no light on the mechanism of this symptom. In general, however, it was found that diarrhœa often, but not always, coexisted with gastric retention and foul eructations. It has been supposed to result from an enteritis due to gastric fermentation. On the whole this symptom caused little complaint—even some small pride in being a "bit too regular."

Foul Eructations

This symptom, not so common as the last—it occurred in 236 patients (36%)—was a source of great embarrassment. Description of the odour varied, but all the patients agreed that it was extremely unpleasant. Most often it was likened to a drain or to rotten eggs. One Scottish patient complained that he had to give up smoking because the gas he eructed was highly inflammable (cf. *Lancet* 1947). It was observed in performing test-meals that the gastric residue often smelt extremely foul. This symptom was closely bound up with gastric retention and ceased in every case as soon as that had been overcome.

Vomiting

238 patients (36%) had vomited on other than isolated occasions, and in 84 cases (13%) vomiting was severe or frequent enough to demand special treatment. The vomiting was characteristically foul and free from bile, typical of the retention syndrome. This symptom also responded rapidly to a gastric-drainage operation.

Fullness

An uncomfortable feeling of fullness in the abdomen after meals was noted in 406 patients (61%). It seldom caused much complaint itself, but it was often associated with pain, foul eructations, and diarrhœa.

Hypoglycæmia

Attacks suggestive of hypoglycæmia, coming on several hours after the last meal and responding to sugar, occurred in 208 patients (31%). On many occasions patients noted the similarity between these attacks and the hypoglycæmia induced by an insulin test-meal.

TABLE II—INSULIN TEST-MEALS IN 61 CASES WITH PROVED RECURRENT ULCERATION

Site of recurrence	Insulin test-meal			
	Strongly positive	Weakly positive	Negative	Unsatisfactory
Duodenal	7	4	—	11
Gastric	2	—	5	12
Jejunal	1	—	—	—
Uncertain	2	—	—	17

Weight

396 patients were weighed at the time of their interview, and their weight was compared with preoperative weight. 95 (24%) had lost weight, 80 (20%) had remained the same, 89 (22%) had gained 1–10 lb., 72 (18%) had gained 11–20 lb., and 60 (15%) had gained more than 20 lb.

Insulin Test-meals

The secretion of hydrochloric acid in response to hypoglycæmia has been recognised as a function of intact vagi (Hollander 1946). This phenomenon has been extensively used as a test for the completeness of vagal section. A dose of soluble insulin varying from 10 to 20 units was injected intravenously in a fasting patient. Samples of gastric contents were aspirated at intervals of ten to fifteen minutes for an hour and a half and titrated for "free" and "total" acidity. A test was accepted as satisfactory only if the following conditions were satisfied:

(1) Hypoglycæmic symptoms were noted. This usually coincided with a blood-sugar level, thirty minutes after the insulin injection, of less than 50 mg. per 100 ml. (Folin and Wu's method). A few cases of insulin sensitivity were found in which severe symptoms were produced and dextrose had to be given intravenously.

(2) No bile was present in most of the specimens.

(3) No food residue was present apart from the first two specimens.

(4) The test was continued for at least an hour.

In this series 450 insulin test-meals were available. 284 tests were made within the first six months after operation. 104 (37%) of these were unsatisfactory; 68 (24%) tests showed little or no rise in free acidity and

TABLE III—RESULTS OF VAGOTOMY RELATED TO INSULIN TEST-MEALS

Insulin test-meal	Excellent	Good	Fair	Poor	Failure	Total
Negative	7 (*10%*)	15 (*20%*)	12 (*15%*)	14 (*19%*)	26 (*35%*)	74 (*100%*)
Weakly positive ..	18 (*23%*)	10 (*12%*)	16 (*20%*)	13 (*17%*)	21 (*25%*)	78 (*100%*)
Strongly positive ..	21 (*23%*)	16 (*18%*)	14 (*15%*)	15 (*16%*)	27 (*28%*)	93 (*100%*)

were regarded as negative, 112 (39%) showed a rise, at 20–40 minutes, of at least 20 ml. of N/10 HCl (0·075% HCl) and were regarded as positive. 40% of these 112 showed a rise to more than 50 ml. of N/10 HCl (0·18% HCl) and were regarded as strongly positive.

166 tests were performed more than six months after operation. Only 16 (10%) of these were unsatisfactory, 47 (28%) were negative, and 103 (62%) were positive, of which 55 were strongly positive. The proportion of negative tests remained much the same, and most of the tests which were unsatisfactory soon after operation were positive later. No case was found in which an indisputably positive test later became negative or vice versa. In all, 330 satisfactory tests were performed on 245 patients. These patients are further considered below.

There is no doubt that some of the tests were positive because of incomplete section of the vagus, but in many cases both anterior and posterior vagal trunks had been sectioned and yet an insulin response was obtained. In these cases it has been assumed that additional vagal fibres have pursued anomalous courses, possibly within the muscle wall of the lower œsophagus (Weinstein et al. 1950).

Clinical results were not closely related to the results of insulin test-meals. Some retention was the rule in the early days after even an incomplete vagotomy, although it tended to recover more quickly than when the vagotomy was complete. On the other hand, symptoms suggesting recurrent ulceration were commoner in patients whose insulin test-meal was positive. Only 5 ulcers were proved to have recurred in the presence of a negative insulin test-meal, and these were all gastric (table II).

Table III shows the correlation of results of insulin test-meals with clinical grading in 245 cases of vagotomy.

When the causes of the failures ("poor" and "failure") were further examined, it was found that significantly more patients with a negative insulin test-meal developed severe gastric retention after vagotomy (sufficient to warrant a secondary drainage operation), and significantly more patients with a strongly positive insulin test-meal were suspected or proved to have a recurrent ulcer. This is shown in tables IV and V.

TABLE IV—ASSOCIATION OF STRONGLY POSITIVE INSULIN TEST-MEAL WITH PROVED OR SUSPECTED RECURRENT ULCERATION

Insulin test-meal	Proved or suspected recurrence	No recurrence	Proportion as percentage
Negative	14	60	23
Weakly positive ..	15	63	24
Strongly positive ..	30	63	48

Gastric Retention

This was present in nearly every patient soon after operation, but in the majority it disappeared within a year. In 98 patients retention was severe enough to demand a subsequent gastric drainage operation. Most of these patients had had a duodenal ulcer, and stenosis contributed to the retention. 21 patients had a normal duodenum, and in them retention was explained on the basis of gastric atony, pyloric spasm, or incoördination of gastric motility. It has been shown kymographically that gastric atony usually passes off within a year after operation (Moore et al. 1947). Pyloric spasm has been observed by Beattie (1950) at operation, but gastroscopically the antrum and pylorus have been seen to be widely open (Paulson and Gladsden 1949, A. M. Gill personal communication). Radiography has shown short-lived shallow ineffective peristaltic waves in these patients.

The drainage operation was gastrojejunostomy in 45 cases, pyloroplasty in 46, and gastrectomy in 7. The further history of these patients is considered below. Retention symptoms responded to operation in all the cases.

Recurrent Ulceration

167 patients (25%) complained of ulcer pain at some time after vagotomy.

X-ray evidence of continued or recurrent ulceration was found in 39 patients radiographed in the first year after operation, and in 26 patients after this time.

TABLE V—ASSOCIATION OF NEGATIVE INSULIN TEST-MEAL WITH SEVERE GASTRIC RETENTION

Insulin test-meal	Severe retention	No severe retention	Proportion as percentage
Negative	26	48	54
Weakly positive ..	19	59	32
Strongly positive ..	12	81	15

Proof of recurrent ulceration was accepted if hæmatemesis or melæna occurred and was unexplained on any other basis, or if an active ulcer was discovered at a subsequent operation. 27 patients had a subsequent hæmorrhage, 3 perforated, and 32 active ulcers were found at operation. Thus the total number of proved recurrences (table VI) was 62 (9·4%), only 2 of which were in women. Of 589 patients on whom vagotomy had been performed for duodenal ulcer 18 recurrent duodenal ulcers were found (3%) and 6 recurrent gastric ulcers (1%). In these cases of gastric ulcer there was evidence of gastric retention. In 12 cases (2%), where hæmorrhage had occurred but no laparotomy was done, the site of the recurrent ulcer was unknown.

In 73 patients whose vagotomy had been performed for gastric ulcer 11 recurrent gastric ulcers were found (15%), and in 2 cases the site of the ulcer was unknown (3%).

In 74 patients whose vagotomy had been performed for jejunal ulcer 4 recurrent duodenal ulcers, 2 recurrent gastric ulcers, and 1 recurrent jejunal ulcer were found, and in 5 cases the site of the recurrence was unknown. The total number of recurrences was 12 (16%).

The only patient with an œsophageal ulcer treated by vagotomy in this series had a proved recurrence of her ulcer.

TABLE VI—62 PROVED RECURRENCES AFTER VAGOTOMY

Vagotomy for	No. of cases	Site of recurrence				
		Duodenal	Gastric	Jejunal	Unknown	Œsophageal

GRADING OF PATIENTS

Each patient has been assessed and placed in one of five grades (modified from Visick 1948): grade I includes patients without gastric symptoms; grade II patients with minor symptoms which may be prevented with the exercise of care; grade IIIs patients whose complaints, though not amenable to prevention, do not interfere with their activities; grade IIIu patients whose symptoms prevent their enjoyment of a full life; and grade IV failures. Grades IIIu and IV are classed as unsatisfactory. The 658 patients followed up were graded as follows:

Grade I,	135 patients *(20%)*
Grade II,	115 patients *(17%)*
Grade IIIs,	123 patients *(19%)*
Grade IIIu,	122 patients *(19%)*
Grade IV,	163 patients *(25%)*

The total number of unsatisfactory results was 285 (44%).

Vagotomy Combined with Gastrojejunostomy

Of 511 patients thus treated 49 had died or were untraced, leaving 462 followed up (table VII). Of the 49 missing patients, 4 (0·8%) had died in the immediate postoperative period, 8 (1·6%) had died later (none from the effects of an ulcer), and 37 (7·6%) were untraced. The 45 patients whose post-vagotomy gastric retention was treated by gastrojejunostomy were included in this group, making a total of 507. These 45 patients were considered only from the standpoint of final assessment. Their *intermediate symptoms belong to the group of* vagotomy alone.

456	408	10	9	43	43	2	2

It is only relative recently that it has been realised that all vagotomies, whether duodenal stenosis is present or not, should be combined with a gastric drainage operation. 78 patients have been assessed less than a year after operation, 215 from one to two years, 135 from two to three years, and only 34 (7%) for more than three years. This is a serious deficiency in the investigation since it is well known that the initial results of gastrojejunostomy alone are usually satisfactory. In this series, however, a higher proportion of unsatisfactory results was found during the first year after operation (15%) than later (8% during the second year, 13% during the third year, and 9% after the third year). This distribution is explained partly by slow recovery from operation and partly by gastric retention during the first year after operation. The incidence of recurrence was low at all times.

FOLLOW-UP FINDINGS

Relief of Pain

This was as striking as when vagotomy alone had been done. As with the vagotomy series, some patients complained later of recurrent abdominal pain. This was suggestive of peptic ulceration in 40 cases (8% of the total series of 507) and bore no resemblance to ulcer pain in 99 cases (20%).

Dysphagia

This occurred in 99 patients (20%) and usually did not last longer than a few weeks.

Diarrhœa

Mild diarrhœa was noted by 161 patients (32%) and severe diarrhœa by 12 (2%). It was much less frequent than in patients who had had a vagotomy alone, and the severe diarrhœa of the post-vagotomy retention syndrome was often cured by gastrojejunostomy. In a few patients there was X-ray evidence of gastric stasis even in the presence of a short circuit, but in most of the patients with mild diarrhœa there was no delay in the emptying of the stomach.

Foul Eructations

Only 19 patients (4%) noticed this symptom, and in each case there was collateral evidence of gastric retention in spite of the gastrojejunostomy.

Vomiting

Nausea and mild occasional vomiting of bile occurred in 130 patients (26%). It was of the same type as the bile vomiting after gastrectomy—i.e., a mouthful of bile without food would be vomited soon after a meal, with relief of nausea. Severe vomiting occurred in only 6 patients (1%).

Fullness

206 patients (41%) complained of uncomfortable epigastric fullness after meals.

Dumping Syndrome

Severe dumping (weakness, &c., immediately after eating) occurred in only 2 patients, but mild attacks of the same type were noticed by 38 patients (8%).

Hypoglycæmia

Attacks very suggestive of hypoglycæmia occurred in 108 patients (21%). These attacks of weakness, faintness, and sweating were quite distinct from the dumping syndrome, coming on, as they did, when the stomach was empty. They were relieved by sugar.

Weight

The weights of 267 patients before and after operation were known. Of these 47 (17%) lost weight, 48 (18%) remained the same, 64 (24%) gained 1–10 lb., 64 (24%) gained 11–20 lb., and 44 (16%) gained more than 20 lb.

Insulin Test-meals

By far the greater number of these were unsatisfactory owing to the presence of bile. 145 meals were studied. Of these 95 were unsatisfactory, 14 were negative, and 36 were positive (of which 17 were strongly positive). No correlation was found between clinical grading and the results of insulin test-meals.

Recurrent Ulceration

In only 40 patients (8%) was there any recurrence of ulcer-type pain. X-ray studies suggested recurrent jejunal ulceration in 5, and recurrent duodenal ulceration in 2, patients in the first year after operation, and jejunal ulceration in 1, and duodenal ulcer in 1, patient after the first year.

Recurrence was proved in 6 patients (1%). In 3 of these, subjected to gastrectomy, the ulcer was jejunal, and in the other 3, who suffered severe gastric bleeding, the site of the ulcer was not proved.

GRADING OF PATIENTS

The 507 patients followed up were graded as follows:

Grade I,	216 *(43%)*
Grade II,	132 *(26%)*
Grade IIIs,	99 *(19%)*
Grade IIIu,	45 *(9%)*
Grade IV,	15 *(3%)*

The total number of unsatisfactory results is 60 (12%).

Vagotomy Combined with Pyloroplasty or Pylorectomy

This was the definitive operation in 235 cases. Pylorectomy was performed by Beattie (1950) in all his recent cases. Pyloroplasty is impossible with a grossly deformed

TABLE VIII—220 PATIENTS TREATED BY SIMULTANEOUS VAGOTOMY AND PYLOROPLASTY

Male				Female			
D.U.		G.U.		D.U.		G.U.	
Total	Follow-up	Total	Follow-up	Total	Follow-up	Total	Follow-up
170	160	29	28	23	21	13	11

duodenum. Of the 235 patients 15 had died or were lost, leaving 220 followed up (table VIII). 46 patients whose post-vagotomy retention syndrome was treated by pyloroplasty or pylorectomy were included in this group, making a total of 266. Of the missing patients 4 (1·7%) died in the immediate postoperative period, 4 died later (none died from the effects of an ulcer), and 7 (3%) were untraced.

As with vagotomy combined with gastrojejunostomy, most of these patients were seen less than two years after their operation. Thus 93 (43% of the 220 cases) were assessed within a year, 97 (44%) between one and two years, 27 (12%) between two and three years, and only 3 (1%) longer than three years after operation.

FOLLOW-UP FINDINGS

Recurrent Pain

15 patients (6% of the total of 266 cases) complained of recurrent pain of ulcer type, and 75 (28%) of abdominal pain of other types.

Dysphagia

The incidence of this symptom was not affected by the additional procedure. 83 patients (31%) remembered having had some dysphagia for a few weeks after operation, and in 2 patients the distress lasted more than six months.

Diarrhœa

This was seldom severe. In fact in only 5 of the 70 patients who admitted to this symptom could it be called distressing. It generally came on soon after operation and seldom persisted for longer than six months. In many cases it coexisted with other signs of gastric retention.

Foul Eructations

14 patients (5%) reported belching foul-smelling gases. This symptom also was usually mild and temporary, and presumably reflected a gastric retention due to atony before the balance between propulsive power of the stomach and calibre of the pylorus and duodenum became established.

Vomiting

This was gratifyingly infrequent. 30 patients (11%) admitted to mild occasional vomiting, usually of food residues, and only 4 patients (2%) vomited frequently.

Fullness

65 patients (24%) complained of feeling full after meals. The reason for this feeling is unknown, but the feeling seems to differ in no way from that of the "small stomach syndrome" after gastrectomy.

Hypoglycæmia

Again this symptom was often noticed—in 92 patients (35%). Its cause is unknown.

Weight

189 patients were weighed and compared with their preoperative weight: 25 (13%) lost weight; in 47 (25%) the weight remained steady; 65 (34%) gained 1–10 lb.; 36 (19%) gained 11–20 lb.; and 16 (8%) gained more than 20 lb. These figures are comparable with those found in the other vagotomy series studied.

Insulin Test-meals

87 insulin test-meals were available for study. Of these 29 (33%) were unsatisfactory, 23 (26%) were negative, and 35 (41%) were positive, of which 19 were strongly positive. No correlation was found between clinical grading and the results of the insulin test-meals.

Recurrent Ulceration

In only 15 patients (6% of the series of 266) has pain suggestive of peptic ulceration recurred. In 1 patient during the first year a gastric ulcer was visible on radiography, and in 2 after the first year there was an appearance of duodenal ulceration on radiography. Recurrence was proved in 2 patients, both of whom had a severe hæmatemesis. In neither case was the site of the ulcer proved.

GRADING OF PATIENTS

The 266 patients followed up were graded as follows:

Grade I,	95 (*36%*)
Grade II,	84 (*32%*)
Grade IIIs,	50 (*19%*)
Grade IIIu,	28 (*10%*)
Grade IV,	9 (*3%*)

The total number of unsatisfactory results was 37 (13%). The figures are very similar to those of vagotomy combined with gastrojejunostomy.

Vagotomy Combined with Limited Partial Gastrectomy

Only 37 patients so treated were followed up, and no details will be given about this small series. Suffice it to say that the results were much more like those of gastrectomy than those of vagotomy, that undesirable side-effects were those associated with gastrectomy, that no instance of proved recurrent ulceration was discovered, and that the clinical grading was as follows:

Grade I,	13 (*34%*)
Grade II,	8 (*22%*)
Grade IIIs,	11 (*30%*)
Grade IIIu,	5 (*14%*)
Grade IV,	0

Summary and Conclusions

1524 cases were analysed, and they fell into two groups:

VAGOTOMY ALONE

Of 736 patients with peptic ulceration treated by vagotomy alone 78 (10·6%) died or were untraced.

Of the 736 patients 73 had been treated for gastric ulcer, with a proved recurrence-rate of 18%.

Of 74 treated for jejunal ulcer the proved recurrence-rate was 16%.

Of 589 treated for duodenal ulcer the proved recurrence-rate was 6%.

Many more patients had symptoms suggesting recurrent ulceration, but the recurrences were not proved.

44% of those studied fell into the "unsatisfactory" group (grades IIIu and IV).

Insulin test-meals revealed a high proportion of positive responses, many of which were probably due to incomplete section of the vagus.

The liability to recurrent peptic ulceration is higher when the insulin test-meal is positive, and the severity of gastric retention greater when the insulin test-meal is negative.

VAGOTOMY WITH DRAINAGE OPERATION

Of 788 patients treated by vagotomy, combined with some drainage operation, 69 (9%) died or were untraced.

Recurrence was proved in only 1% of these cases. Only in 7% were there symptoms suggesting recurrence.

The results were classified as unsatisfactory in 12% of these cases.

It is concluded that vagotomy alone is an unsatisfactory operation. Vagotomy combined with a gastric drainage operation yields much better immediate results;

but this procedure will stand or fall by the proved recurrence-rate over a number of years.

This investigation was suggested by Mr. H. W. Burge, M.B.E., F.R.C.S. It would have been impossible but for the generous coöperation of surgeons throughout the country, who have given me free access to their case-records and permission to follow up their patients. The work was done during the tenure of a Dan Mason research fellowship at the West London Hospital Medical School.

CALCINOSIS UNIVERSALIS
TREATED WITH ADRENOCORTICOTROPHIC HORMONE AND CORTISONE

J. N. Briggs
M.D. Lond., M.R.C.P., D.C.H.
MEDICAL REGISTRAR, CHILDREN'S HOSPITAL, SHEFFIELD

R. S. Illingworth

PROFESSOR OF CHILD HEALTH IN THE UNIVERSITY OF SHEFFIELD

DESPITE the infrequency of calcinosis universalis many papers on it have been published in the last forty years. Those of Brooks (1934) and Atkinson and Parkes Weber (1938) gave comprehensive reviews of earlier literature, the latter authors listing 78 publications before 1938.

The association of calcinosis with scleroderma was probably first noted by Meachen (1903). Atkinson and Weber (1938) concluded that this association occurred in about a third of all cases of calcinosis.

Numerous treatments have been used, including disodium hydrogen phosphate (Craig and Lyall 1931), heliotherapy (Schultze 1927), ammonium chloride with a low-calcium diet (Bauer et al. 1931), sodium nitrate and intravenous calcium (Roovers 1939), low-calcium diet (Brooks 1934), and thyroid extract (Weissenbach 1913). Sheldon (1936, 1938), described a spontaneous cure.

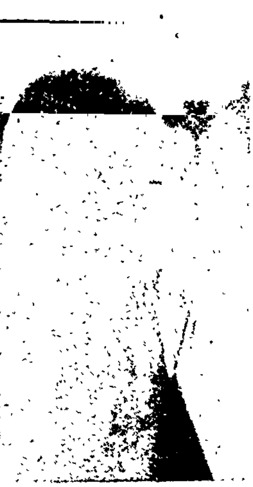

Fig. 2—Same shoulder as in fig. 1 after A.C.T.H. (a very small piece of tissue was removed for biopsy) (case 1).

In the two cases described below we used adrenocorticotrophic hormone (A.C.T.H.) and cortisone.

CASE-RECORDS

Case 1.—A girl, aged 4 years when first seen in 1949, had three weeks' history of stiffness of the arms, so that she could not feed or dress herself and had difficulty in walking and stooping.

Clinical Findings and Progress

On examination both her arms were swollen and her skin was shiny. There was obvious pitting œdema. Her face was violaceous. She had a well-marked reticular mottling of the face, limbs, and buttocks. There was some œdema of the lower limbs. Nothing abnormal was found elsewhere.

Dermatomyositis was diagnosed, and the patient admitted to hospital for biopsy, which confirmed the diagnosis and showed that the principal site of the lesion was in the muscle-fibres, which were degenerating. Radiographs taken at the time were regarded as normal, but further study of them later showed two small deposits of calcium, one in the right arm and one in the right loin.

During April, 1951, several small subcutaneous nodules, which felt calcareous, began to appear around the shoulders (fig. 1) and thighs. The patient was readmitted, and further radiography showed the presence of considerable deposits of calcium, chiefly in the subcutaneous tissues of the neck, shoulders, and buttocks, and in the fascial planes of the gluteal muscles and the adductor and abductor muscles of the thighs.

Another biopsy showed that calcium was present in the superficial layer of the skin (fig. 7) in close association with several collagenous masses. Foamy cells were present in small crypts between the collagenous and calcified areas. There appeared to be a transition between the collagen and calcified material which was not an inflammatory change.

The use of adrenocorticotrophic hormone was considered, but it was decided to delay this until the child had been observed for a further period of six months to determine whether the condition would progress, remain stationary, or resolve. At the end of six months it was evident both clinically and radiologically that her condition was worse. She was less mobile, more nodules had appeared on her elbows and in her neck, and a flexure contracture of her right tendo Achillis had developed. Radiography showed a considerable extension of the deposits in the interfascial planes (figs. 3 and 5).

Treatment with A.C.T.H.

The patient received A.C.T.H. between August and October, 1951. The dosage was 100 mg. on the first day, 50 mg. on the second, and 30 mg. on the third, followed by 20 mg. daily. Each daily total dose was given intramuscularly in divided amounts six-hourly. The total dosage was 1000 mg. As a result of this treatment the eosinophil-count fell from 510 per c.mm. to 38 per c.mm. in seven days. No change was noted in the serum chemistry, the serum-calcium and

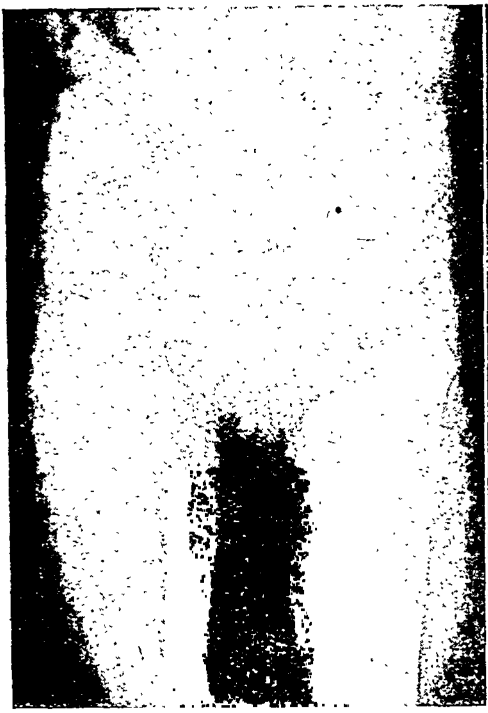

Fig. 3—Deposits of calcium in tissues of lower limb before A.C.T.H. (case I).

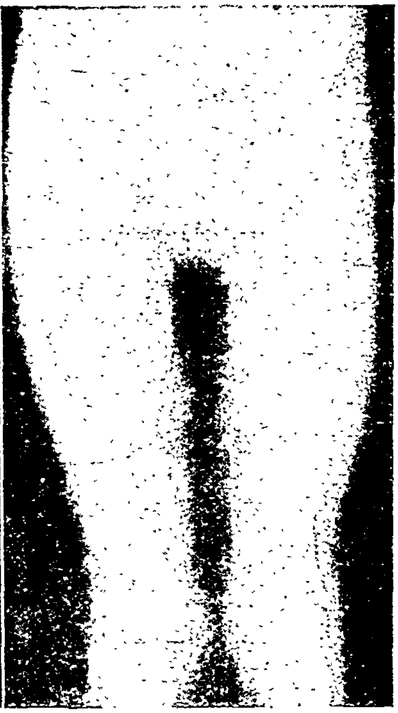

Fig. 4—Lower limbs after A.C.T.H. (case I)

serum-phosphorus levels remaining normal (table I). During the second week of treatment she became unwell, and her subcutaneous lesions became inflamed but did not break down. After five days she improved and her subcutaneous lesions were found to have become softer and smaller. Radiography at the end of the course showed considerable improvement had occurred, with clearing of large areas of calcium deposits, especially around the pelvic girdle. Another skin biopsy confirmed the disappearance of calcium and a regression of the collagenous material previously present.

Although the response to the first course of A.C.T.H. was striking, the calcium deposits had not entirely disappeared. Because of this it was felt that a further course of the hormone was essential if the condition was to be cured. A.C.T.H. therapy was begun again in December, 1951. The hormone was given in divided doses four times a day by the intramuscular route to a total of 2000 mg. in six weeks. Radiography at the end of the course (figs. 4 and 6) showed that almost all the calcium deposits had now disappeared.

The girl is being followed up in the outpatient department and has so far remained well. In October, 1952, nine months after treatment was completed, X-ray studies showed no further deposition of calcium.

Biochemical Findings

The results of the biochemical estimations are summarised in table I.

Calcium-balance estimations while the patient was on a known dietary intake were carried out before and during the courses of A.C.T.H. On a low-calcium intake of 65 mg. a day before treatment with A.C.T.H. the patient was in negative balance. During the course of A.C.T.H. the result on the same diet was almost identical. From a study of these balances no evidence of increased loss of calcium in the urine could be detected. Unfortunately further estimations of calcium balances on a normal calcium intake before and during the second course of A.C.T.H. were technically unsatisfactory.

Case 2.—A girl, aged 13, was well until 1942 when, after an attack of mumps, several small swellings were noted in the skin overlying her popliteal fossæ. Shortly afterwards others appeared in the skin over her shoulders, elbows, buttocks, and groins.

Clinical Findings and Progress

She was seen at the Children's Hospital in 1943, and the diagnosis of calcinosis universalis was confirmed by radiography. The lesions were both subcutaneous and in the fascial planes of her limbs and buttocks. They were extensive around her shoulders, elbows, pubis, thighs, and ankles. During 1943–44 she began to have episodes in which subcutaneous nodules became red and indurated. Later they broke down and discharged a creamy white substance and left sinuses which tracked down to the deep fascial layer. These episodes have persisted with increasing frequency, leading to severe scarring and contractures, as a result of which she cannot stand unaided. Throughout 1942–52 the deposits of subcutaneous calcium and the plaques in the fascial planes have steadily increased.

Treatment with Cortisone

She was admitted to the Children's Hospital in 1951, and a course of cortisone was begun on Oct. 31. The hormone was given orally: 250 mg. on the first day, 200 mg. on the second, 100 mg. on the third, and thereafter 50 mg. daily. Her general condition remained unchanged, and her serum chemistry did not alter. Her eosinophil response was

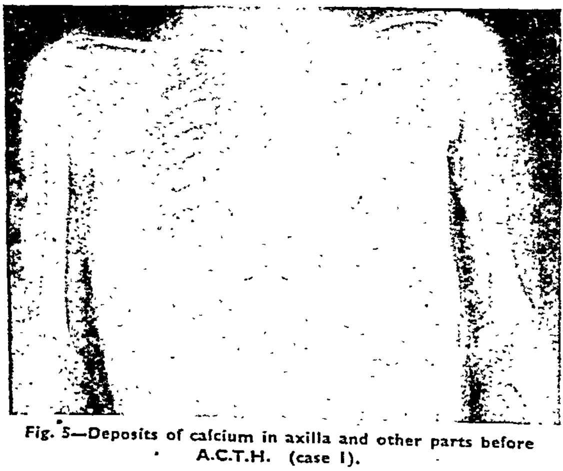

Fig. 5—Deposits of calcium in axilla and other parts before A.C.T.H. (case I).

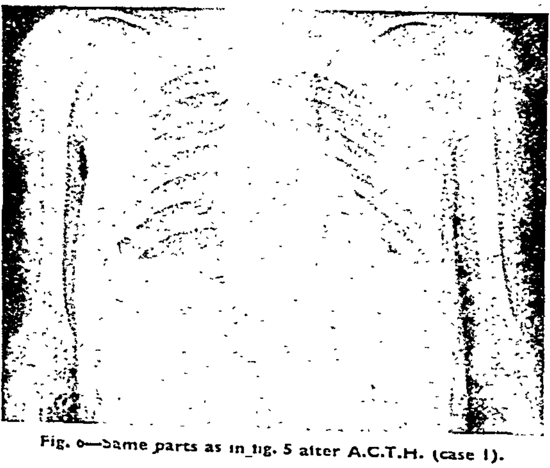

Fig. 6—Same parts as in fig. 5 after A.C.T.H. (case I).

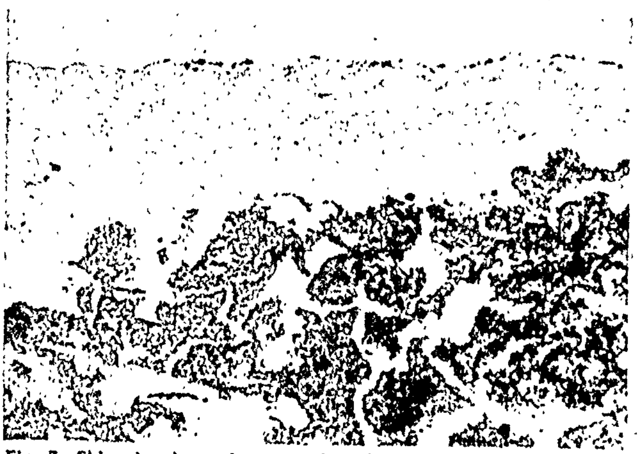

Fig. 7—Skin showing calcareous deposits, shown in black (case 1) (Von Kossa).

unsatisfactory. At the end of a course of 2425 mg. there was no apparent improvement in her clinical state, and further radiography showed that the calcium deposits were unchanged.

Treatment with A.C.T.H.

On Dec. 8, 1951, an intramuscular course of A.C.T.H. was begun. The dosage was 200 mg. on the first day, 100 mg. on the second, and thereafter 50 mg. daily. The eosinophil-count fell from 63 to 6 per c.mm. in five days. Slight insignificant variations occurred in the serum-calcium, serum-phosphorus, and serum-alkaline-phosphatase levels. When the patient had received 1075 mg. of A.C.T.H., there was no clinical or radiological evidence of improvement. She is being followed up as an outpatient, and her condition is slowly deteriorating.

Biochemical Findings

Table II summarises the biochemical investigations.

The daily urinary output of calcium was estimated for a week before and during the course of hormone therapy (table III). The diet was kept constant. Although the figures do not cover the whole period of therapy they suggest that, after an initial decrease in calcium excretion during treatment with cortisone, there was a rise during the third week. During the first week of A.C.T.H. therapy the urinary calcium output was increased to three times that seen during the week before any hormone treatment.

DISCUSSION

It is always difficult to assess the use of a drug in conditions in which spontaneous cures are possible. Spontaneous cure of calcinosis universalis however, is exceedingly rare, and in case 1 there had been a progressive deposition of calcium for two years. In the last six months of this period we took serial radiographs at intervals to be sure that the calcium was not disappearing spontaneously. These films showed undoubted evidence of increasing deposition of calcium. After this long period of observation, A.C.T.H. was given, and within two or three weeks there was an obvious reduction in the size of the subcutaneous nodules, and the clinical impression that improvement was taking place was amply confirmed by radiography. At the end of the first course of A.C.T.H. the radiographs showed a striking disappearance of the calcareous deposits. The girl was next observed for a further two months, and during this period there was no further clinical or radiological evidence of the disappearance of the deposit. After a second course was completed the further improvement was just as striking as before, with the result that the calcium had almost completely disappeared. Though one cannot be certain, the evidence is very strong that the disappearance of calcium was the direct result of the A.C.T.H.

There was no evidence of any improvement in case 2. The failure of A.C.T.H. in this girl may perhaps have been related to the long duration of the disease before treatment was started.

It is unfortunate that the biochemical investigations do not throw any light on the processes involved in the course of calcinosis under A.C.T.H. treatment. There seemed to be a transitory increase of calcium excretion in case 2 under cortisone and under A.C.T.H., but we are not satisfied with this evidence. It is particularly unfortunate that biochemical data are lacking in the second course of A.C.T.H. in case 1. We fully realise that the balance studies in both cases are inadequate, but we felt that they should be summarised because they may be of interest to others studying similar cases.

TABLE III—URINARY CALCIUM OUTPUT IN CASE 2

Weekly periods	Total calcium (mg.)
Before therapy	656·2
1st week cortisone	344·1
2nd week cortisone	353·4
3rd week cortisone	911·7
4th week cortisone	Insufficient data
5th week cortisone	Insufficient data
1st week A.C.T.H.	2881·5
2nd week A.C.T.H.	350·0
3rd week A.C.T.H.	Insufficient data
4th week A.C.T.H.	Insufficient data

SUMMARY

Two cases of calcinosis universalis were treated by A.C.T.H.; one had had a previous course of cortisone.

One of these cases, in which the calcinosis followed dermatomyositis, appeared to respond dramatically to A.C.T.H., almost all calcium deposits disappearing during the course of treatment. The second case, of many years' duration and unrelated to dermatomyositis, did not respond.

We wish to thank Dr. J. L. Emery for the histological studies, and Miss E. Finch for the biochemical investigations.

ANTIGENIC EFFICIENCY OF FLUID AND PRECIPITATED DIPHTHERIA PROPHYLACTICS

IN VERY YOUNG BABIES AND LAMBS

From the Wellcome Research Laboratories, Beckenham; the Wellcome Veterinary Research Station, Frant; and Farnborough Hospital, Kent

It was shown by Barr, Glenny, and Randall (1950) that babies could be successfully immunised by two doses, each 0·5 ml. (25 Lf doses), of alum-precipitated toxoid (A.P.T.), if the level of their maternally conferred antitoxin had fallen below 0·04 unit per ml. at the time of the first injection. Among babies with levels below 0·02 unit per ml. at this time, the response to immunisation seemed better among those first injected when 6–13 weeks than in those first injected after the age of 6 months. This was attributed to the dose of prophylactic per body-weight being greater, and the total circulating passive antitoxin less, in the younger babies in relation to antitoxin titre per millilitre. Very young babies were not investigated. Vahlquist (1949), however, showed that infants born without any passively conferred antitoxin could be immunised at birth with 1 ml. (45 Lf doses) of A.P.T., though the response might be somewhat delayed. It is probably now generally accepted that failure to immunise very young babies is due rather to interference by maternally conferred antitoxin than to their physiological inability to respond.

IMMUNISATION OF BABIES

We have now investigated the effect of immunisation of very young babies born with passive maternally conferred antitoxic titres below 0·02 unit per ml.: most of these titres were below 0·001 unit per ml. One group received two intramuscular injections, each 0·5 ml. (25 Lf doses), of A.P.T. separated by an interval of 8–9 weeks. The other group had three intramuscular injections, each of 25 Lf doses, of purified toxoid, separated by intervals of a month. This toxoid, prepared by Dr. Linggood, contained about 1800 Lf doses per mg. of nitrogen. The first injection was given to all the babies when they were 6–10 days old. Blood samples were taken 7–10 (usually 8) weeks after the last injection and were titrated for antitoxin content by the guineapig intracutaneous method (Römer and Sames 1909) as modified by Glenny and Llewellyn-Jones (1931). Titrations were made at approximately twofold differences and titres recorded, for example, as 0·02 unit were over 0·02 but under 0·05 unit per ml. In the calculation of geometric means of groups each value was taken as the geometric mean of the limits between which it lay.

The results of these tests are shown in table I, which includes the titres of a group of older babies immunised with two doses of A.P.T. given intramuscularly at an interval of 6–9 weeks; these figures have been taken from the earlier work of Barr et al. (1950). Also included in this table are the titres of six babies, immunised with purified toxoid, who received the first dose when 7 months of age or older. Two facts are at once evident from this table: first, that the response of babies first injected with A.P.T. when 6–10 days old was as good as that of babies first injected at the age of 6 weeks or more; and, secondly, that the response of very young babies to three injections of toxoid was definitely inferior to that of babies of the same age to two injections of A.P.T. At least two factors might contribute to this result: very young babies may not respond well to unprecipitated prophylactics, and the intervals between the injections of toxoid may have been ill chosen.

We have been unable to test the first of these suggestions adequately, but it is perhaps significant that none of the very few babies immunised with toxoid at the age of 7 months or more (group D in table I) failed to produce any detectable antitoxin. Nearly half the very young babies had titres below 0·01 unit per ml. at the time of sampling; none of the six older babies had such low titres. It is clearly impossible to draw any definite conclusions on such small numbers, but the results suggest that age at the time of the first injection may have a considerable effect on the response to immunisation with fluid purified toxoid. Further work is needed.

So far as we are aware, no careful study has been made to determine the best procedure to adopt in a course of primary immunisation involving three injections. It is clear on theoretical grounds that the optimal intervals between the first and second and between the second and third doses must depend on the degree of basal immunity established by the first injection. If this were poor, it might be advisable to use the second injection as a reinforcing primary stimulus and inject it 7–10 days after the first; the third injection might then be delayed for 4 or more weeks. A procedure of this kind was suggested for the immunisation of adults by Barr and Glenny (1951). It appears probable that the basal immunity established by the first injection of toxoid in the young babies of group C was of a low order.

IMMUNISATION OF GUINEAPIGS

Good immunity was produced in guineapigs by only two injections of this batch of purified toxoid. Table II shows the antitoxin titres of guineapigs 10 days after the second of two subcutaneous injections of A.P.T. and of purified toxoid, given 28 days after the first. Slightly better immunity was produced by two injections each of 1 Lf dose of A.P.T. than by two injections of the same amount of purified toxoid. The difference between the means of the logarithms of the titres in the two groups is not significant ($t = 1{\cdot}599$, $P = 0{\cdot}1$–$0{\cdot}2$), but the scatter of titres among the animals immunised with toxoid was considerably greater, and some failures might therefore be expected in the immunisation of a large population of animals with this material. It is nevertheless clearly evident that the difference between the responses of

TABLE I—ANTITOXIN TITRES OF BABIES 7–10 WEEKS AFTER IMMUNISATION

Group	Age at 1st injection	No. of babies and antitoxin titres (units/ml.)										Total	Geometric mean
		<0·005	0·005	0·01	0·02	0·05	0·1	0·2	0·5	1·0	2·0		
A	6 weeks or more	..	..	..	1	5	9	22	6	..	..	43	0·237
B	6–10 days	..	..	..	2	0	4	10	7	..	..	23	0·286
C	6–10 days	6	2	1	2	1	1	2	..	..	..	15	..
D	7 months or more	..	..	2	1	0	0	1	1	0	1	6	0·128

Groups A and B received two injections, each of 25 Lf doses of A.P.T., and groups C and D three injections, each of 25 Lf doses of purified toxoid.

TABLE II—ANTITOXIN TITRES OF GUINEAPIGS 10 DAYS AFTER SECOND INJECTION OF DIPHTHERIA PROPHYLACTIC GIVEN 28 DAYS AFTER FIRST INJECTION

Type of prophylactic	Size of dose	No. of guineapigs and antitoxin titres (units/ml.)									Geometric mean
		0·1	0·2	0·5	1·0	2·0	5·0	10	20	50	
A.P.T.	1 Lf	..	..	..	1	2	17	8	2	..	8·44*
Toxoid	1 Lf	1	1	1	0	4	6	4	1	1	5·17*
Toxoid	2·5 Lf	..	..	..	1	5	7	15	1	..	14·13

* t = 1·599, P = 0·1–0·2

guineapigs to two injections of these prophylactics is not of the same order as the difference between the responses of very young babies to two injections of A.P.T. and to three injections of toxoid. Considered in relation to body-weight, each dose given to the babies was about double that given to the guineapigs that received 1 Lf dose at each injection. The last line in table II shows the antitoxic titres of guineapigs that received two injections, each of 2·5 Lf doses, of the same batch of purified toxoid as those in line 2. This dose is comparable with that received by the young babies (group C in table I); but, whereas these babies had three injections, the guineapigs had only two. It therefore appears from the data contained in tables I and II that two doses of purified toxoid or of A.P.T. produce the same order of immunity in guineapigs, but that two doses of A.P.T. produce far better immunity in very young babies than do three doses of purified toxoid. No comparison can be made between the actual titres of the guineapigs and the babies, because the guineapigs were bled at the peak of the response to the second injection and the babies were bled considerably later. The titres of the guineapigs would be about half to a quarter of those recorded in table II if tested about two months after the second injection.

IMMUNISATION OF YOUNG LAMBS AND OF SHEEP

Some of us, in collaboration with other colleagues, have already found that lambs injected on the day of birth with 250 Lf doses of A.P.T. produced antitoxin within 3 weeks without further injection (unpublished). In the present work the two prophylactics A.P.T. and purified toxoid were compared in newborn lambs and in sheep. These animals were immunised either by two injections, each 250 Lf doses, of A.P.T. or by three injections, each 250 Lf doses, of purified toxoid; intervals between injections were all 28 days. Considered in relation to body-weight the lambs received on the average nearly twenty times the doses given to the sheep. Blood samples were taken before injection to confirm the absence of normal antitoxin, and 14 days after each injection; additional samples were taken after the first dose. Some antitoxin was produced by all the lambs and all the sheep by the 28th day after the first injection of A.P.T.; a response was detected in most cases by the 14th day. This rapid response cannot be taken as indicating potential immunity already present in these animals, for the titres continued to rise after the 14th day in the manner typical of primary responses. No lambs and only three out of ten sheep produced any detectable antitoxin after the first injection of purified toxoid; the responses of the three sheep were again of the primary type.

Table III shows the antitoxin titres of all the animals at different times during immunisation. Several points of interest emerge from the results obtained from these small groups. It is at once apparent that, in both the lambs and the sheep, much better immunity was established by two injections of A.P.T. than by three injections of purified toxoid. It will also be noted that one injection of A.P.T. produced higher antitoxic titres in sheep than did three injections of toxoid.

A comparison of the titres produced after injection with A.P.T. shows that the responses of the sheep were significantly better than those of the lambs. This was the case when comparing titres 28 days after the first injection ($t = 2{\cdot}907$, $P = <0{\cdot}01$) or 14 days after the second injection ($t = 2{\cdot}871$, $P = 0{\cdot}01$). In contrast to this result, there is a strong suggestion that the responses of the lambs to three injections of purified toxoid were better than those of the sheep. The titres, however, of these small groups of animals (last two columns in table III) showed a large scatter.

Many of the results appear conflicting, and it must be remembered that the same dosage was used for immunisation of the sheep as for the newborn lambs. The response to the first injection of A.P.T. was more rapid in the sheep, all of which had some circulating antitoxin by the 14th day after injection; only three of the nine lambs had developed antitoxin so soon after injection. Owing to the very great difference in weight between the sheep and the lambs, the optimum interval between the two injections of A.P.T. would not be the same for both and would be expected to be greater for the smaller animals. In relation to body-weight the dose received by the sheep was of the same order as that given to the guineapigs, and equal to about an eighteenth of that injected into the lambs. It is reasonable to suppose that the responses of the lambs would have compared more favourably with those of the sheep if they had received the second dose at a longer interval than one month after the first: the larger dose, in terms of body-weight, would favour a longer interval.

TABLE III—ANTITOXIN TITRES OF LAMBS AND SHEEP AFTER IMMUNISATION WITH A.P.T. AND WITH PURIFIED TOXOID

5·0	..	..	1	3	..	..
10	..	..	..	3	..	..

Much work could profitably be done, especially on the optimum intervals between injections of different types of prophylactic. Little is known of the duration of immunity in babies after primary immunisation, and antitoxic titres 2 or 6 months after the second injection of the course may give a false idea of the amount of permanent antitoxin produced by the course. The effect of rapid growth on permanent production is unknown: possibly the rate of production may only become constant when body-weight remains constant, or antitoxin-producing cells may increase during growth.

In the work recorded here only one batch of purified toxoid was used. It is now well known that qualitative differences exist between batches of toxoids (see Barr and Glenny 1949): these differences are reduced after precipitation of the toxoids with alum or by adsorption on to a suitable carrier. The unexpected results obtained may not be typical of all fluid preparations, but they emphasise the need for controlling changes in procedure whether of type of prophylactic or spacing of injections.

SUMMARY

Diphtheria antitoxic titres of the same order were produced in babies by two injections, each 25 Lf, of A.P.T. given at an interval of about 2 months, whether the first injection was given when the babies were aged 6–10 days or 6 weeks or more.

Babies given a first injection of purified toxoid at the age of 6–10 days, and two other similar injections at monthly intervals thereafter, developed poor immunity. Better results were obtained in a very few babies given the first injection of three at the age of 7 months.

Two doses of 1 Lf of purified toxoid given at an interval of 4 weeks produced similar titres in guineapigs to those following two injections of 1 Lf of A.P.T. The scatter of titres after toxoid was, however, considerably greater.

Sheep injected with 250 Lf doses of A.P.T. produced higher antitoxic titres than newborn lambs 28 days after injection. This result was also obtained 10 days after a second similar injection.

After three injections of purified toxoid given at monthly intervals newborn lambs tended to have higher antitoxic titres than sheep, but the antitoxin titres were widely scattered.

MEASUREMENT OF IODIDE-CONCENTRATING POWER AS A TEST OF THYROID FUNCTION

G. A. NEWSHOLME
M.D. Camb., M.R.C.P.
SENIOR MEDICAL REGISTRAR, UNITED BIRMINGHAM HOSPITALS

It has been shown that, even after synthesis of thyroid hormone has been prevented by the administration of thiouracil, the thyroid gland of the rat can still concentrate iodine (Taurog et al. 1947, Vanderlaan and Vanderlaan 1947). Under these conditions the iodine is concentrated as iodide, the amount contained by the gland at any given moment being proportional to the plasma-iodide level at that time. Between the thyroid gland and the plasma there is a gradient for iodide which remains constant over a wide range of plasma-iodide levels.

Stanley and Astwood (1948), producing evidence that the same holds true for man, have suggested that the amount of radioactive iodine accumulated by the thyroid gland after a dose of the antithyroid drug 2-mercapto-imidazole might be used as a measure of thyroid activity. Foss and Herbert (1952), using a modification of Stanley and Astwood's technique, found it, as a test for thyrotoxicosis, as useful as the thyroid iodide clearance.

Childs et al. (1950), investigating in man the effect of increasing amounts of inert iodide "carrier" on the behaviour of a tracer dose of radioactive iodine, showed that amounts of about 5–10 mg. of sodium iodide modified the uptake of radio-iodine by the thyroid gland in a similar way to thiouracil. The radio-iodine, being accumulated in the form of iodide, could be almost completely discharged from the thyroid gland by a dose of sodium thiocyanate. Sodium iodide in doses of this order appears to inhibit the binding of iodine to protein without saturating the iodide-concentrating mechanism of the gland.

This paper sets out the result of 86 tests done by a method similar to that of Stanley and Astwood.

METHOD

86 subjects were tested in two groups. The first group totalled 32 and comprised 12 normal volunteers between the ages of twenty and sixty-five with no history or evidence of thyroid disease, 7 patients with clinical thyrotoxicosis, and 13 patients referred for testing as possible cases of thyrotoxicosis. To these methylthiouracil 400 mg. was given by mouth four hours or more after their last preceding meal, followed an hour later by an oral dose of 35 μC of carrier-free radio-iodine.

The second group totalled 54 cases and comprised 10 normal people, 12 patients with thyrotoxicosis, and 32 patients referred for diagnosis. To these the tracer dose of 35 μC of radio-iodine was given intravenously together with 10 mg. of sodium iodide in a volume of 2 ml.

After the tracer dose counting-rates over the neck and thigh were followed until the highest count was reached, and usually for longer.

The neck was counted at a fixed distance of 20 cm. from the skin over the cricoid cartilage to the central wire of a G10 Pb counter (20th Century Electronics Ltd.) enclosed in a lead collimator 2 cm. in effective thickness. A window with an aperture 6×11 cm. at a distance of 6 cm. from the central wire exposed the whole length of the cathode to gamma rays.

The patients were seated on a chair of adjustable height in front of a lead screen 1·5 cm. thick. The counter "viewed" the neck through an opening 15×11 cm. in the screen below a rest on which the chin was placed.

Thigh counts were made with the same counter placed on a shelf 45 cm. from the ground so that the person could sit with the legs together and the outer side of one thigh pressed with its mid-point against the centre of the counter window.

RESULTS

Typical counts over neck and thigh are shown for one normal and one thyrotoxic subject from the first group in fig. 1. The counting-rates reach a maximum within two or three hours, after which, in these two cases, sodium thiocyanate 1 g. was given intravenously to discharge radio-iodine from the thyroid gland. The fall in counting-rate over the neck and the radioactivity remaining give some indication of the extent to which binding of the tracer dose to protein has taken place. Part of the counting-rate over the neck is due to radio-iodine in tissues other than the thyroid gland. The neck count falls sharply after a dose of thiocyanate, and in the thyrotoxic patient is accompanied by a rise in the thigh count which is due to the discharge

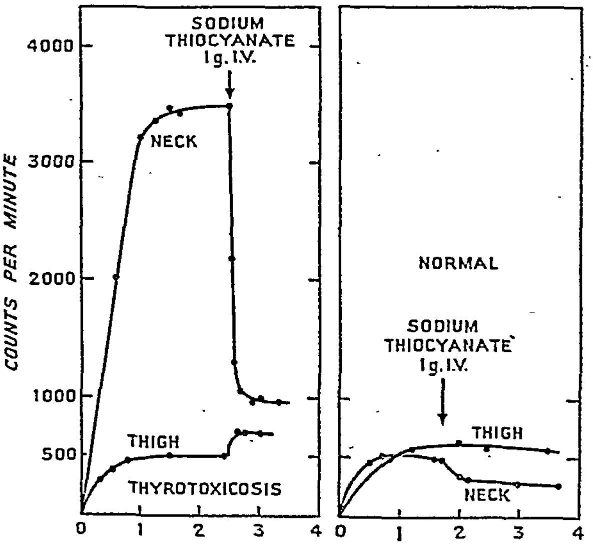

Fig. 1—Neck and thigh counting-rates for 1 thyrotoxic patient and 1 normal person after an oral dose of carrier-free radio-iodine. Methylthiouracil 400 mg. was given an hour beforehand in each case.

TABLE II—ANTITOXIN TITRES OF GUINEAPIGS 10 DAYS AFTER SECOND INJECTION OF DIPHTHERIA PROPHYLACTIC GIVEN 28 DAYS AFTER FIRST INJECTION

Type of prophylactic	Size of dose	No. of guineapigs and antitoxin titres (units/ml.)									Geometric mean
		0·1	0·2	0·5	1·0	2·0	5·0	10	20	50	
A.P.T.	1 Lf	..	..	..	1	2	17	8	2	..	8·44*
Toxoid	1 Lf	1	1	1	0	4	6	4	1	1	5·17*
Toxoid	2·5 Lf	..	..	..	1	5	7	15	1	..	14·13

* t = 1·599, P = 0·1–0·2

guineapigs to two injections of these prophylactics is not of the same order as the difference between the responses of very young babies to two injections of A.P.T. and to three injections of toxoid. Considered in relation to body-weight, each dose given to the babies was about double that given to the guineapigs that received 1 Lf dose at each injection. The last line in table II shows the antitoxic titres of guineapigs that received two injections, each of 2·5 Lf doses, of the same batch of purified toxoid as those in line 2. This dose is comparable with that received by the young babies (group C in table I); but, whereas these babies had three injections, the guineapigs had only two. It therefore appears from the data contained in tables I and II that two doses of purified toxoid or of A.P.T. produce the same order of immunity in guineapigs, but that two doses of A.P.T. produce far better immunity in very young babies than do three doses of purified toxoid. No comparison can be made between the actual titres of the guineapigs and the babies, because the guineapigs were bled at the peak of the response to the second injection and the babies were bled considerably later. The titres of the guineapigs would be about half to a quarter of those recorded in table II if tested about two months after the second injection.

IMMUNISATION OF YOUNG LAMBS AND OF SHEEP

Some of us, in collaboration with other colleagues, have already found that lambs injected on the day of birth with 250 Lf doses of A.P.T. produced antitoxin within 3 weeks without further injection (unpublished). In the present work the two prophylactics A.P.T. and purified toxoid were compared in newborn lambs and in sheep. These animals were immunised either by two injections, each 250 Lf doses, of A.P.T. or by three injections, each 250 Lf doses, of purified toxoid; intervals between injections were all 28 days. Considered in relation to body-weight the lambs received on the average nearly twenty times the doses given to the sheep. Blood samples were taken before injection to confirm the absence of normal antitoxin, and 14 days after each injection; additional samples were taken after the first dose. Some antitoxin was produced by all the lambs and all the sheep by the 28th day after the first injection of A.P.T.; a response was detected in most cases by the 14th day. This rapid response cannot be taken as indicating potential immunity already present in these animals, for the titres continued to rise after the 14th day in the manner typical of primary responses. No lambs and only three out of ten sheep produced any detectable antitoxin after the first injection of purified toxoid; the responses of the three sheep were again of the primary type.

Table III shows the antitoxin titres of all the animals at different times during immunisation. Several points of interest emerge from the results obtained from these small groups. It is at once apparent that, in both the lambs and the sheep, much better immunity was established by two injections of A.P.T. than by three injections of purified toxoid. It will also be noted that one injection of A.P.T. produced higher antitoxic titres in sheep than did three injections of toxoid.

A comparison of the titres produced after injection with A.P.T. shows that the responses of the sheep were significantly better than those of the lambs. This was the case when comparing titres 28 days after the first injection ($t = 2{\cdot}907$, $P = <0{\cdot}01$) or 14 days after the second injection ($t = 2{\cdot}871$, $P = 0{\cdot}01$). In contrast to this result, there is a strong suggestion that the responses of the lambs to three injections of purified toxoid were better than those of the sheep. The titres, however, of these small groups of animals (last two columns in table III) showed a large scatter.

Many of the results appear conflicting, and it must be remembered that the same dosage was used for immunisation of the sheep as for the newborn lambs. The response to the first injection of A.P.T. was more rapid in the sheep, all of which had some circulating antitoxin by the 14th day after injection; only three of the nine lambs had developed antitoxin so soon after injection. Owing to the very great difference in weight between the sheep and the lambs, the optimum interval between the two injections of A.P.T. would not be the same for both and would be expected to be greater for the smaller animals. In relation to body-weight the dose received by the sheep was of the same order as that given to the guineapigs, and equal to about an eighteenth of that injected into the lambs. It is reasonable to suppose that the responses of the lambs would have compared more favourably with those of the sheep if they had received the second dose at a longer interval than one month after the first: the larger dose, in terms of body-weight, would favour a longer interval.

TABLE III—ANTITOXIN TITRES OF LAMBS AND SHEEP AFTER IMMUNISATION WITH A.P.T. AND WITH PURIFIED TOXOID

Antitoxin titre (*units/ml.*)	No. of animals					
	28 days after one injection of A.P.T.		14 days after second injection of A.P.T.		14 days after third injection of toxoid	
	Lambs	Sheep	Lambs	Sheep	Lambs	Sheep
0·002	..	..	..	..	1	2
0·004	1	..	..	..	0	1

10	..	..	..	3	..	..

Much work could profitably be done, especially on the optimum intervals between injections of different types of prophylactic. Little is known of the duration of immunity in babies after primary immunisation, and antitoxic titres 2 or 6 months after the second injection of the course may give a false idea of the amount of permanent antitoxin produced by the course. The effect of rapid growth on permanent production is unknown: possibly the rate of production may only become constant when body-weight remains constant, or antitoxin-producing cells may increase during growth.

In the work recorded here only one batch of purified toxoid was used. It is now well known that qualitative differences exist between batches of toxoids (see Barr and Glenny 1949): these differences are reduced after precipitation of the toxoids with alum or by adsorption on to a suitable carrier. The unexpected results obtained may not be typical of all fluid preparations, but they emphasise the need for controlling changes in procedure whether of type of prophylactic or spacing of injections.

SUMMARY

Diphtheria antitoxic titres of the same order were produced in babies by two injections, each 25 Lf, of A.P.T. given at an interval of about 2 months, whether the first injection was given when the babies were aged 6–10 days or 6 weeks or more.

Babies given a first injection of purified toxoid at the age of 6–10 days, and two other similar injections at monthly intervals thereafter, developed poor immunity. Better results were obtained in a very few babies given the first injection of three at the age of 7 months.

Two doses of 1 Lf of purified toxoid given at an interval of 4 weeks produced similar titres in guineapigs to those following two injections of 1 Lf of A.P.T. The scatter of titres after toxoid was, however, considerably greater.

Sheep injected with 250 Lf doses of A.P.T. produced higher antitoxic titres than newborn lambs 28 days after injection. This result was also obtained 10 days after a second similar injection.

After three injections of purified toxoid given at monthly intervals newborn lambs tended to have higher antitoxic titres than sheep, but the antitoxin titres were widely scattered.

MEASUREMENT OF IODIDE-CONCENTRATING POWER AS A TEST OF THYROID FUNCTION

G. A. NEWSHOLME
M.D. Camb., M.R.C.P.
SENIOR MEDICAL REGISTRAR, UNITED BIRMINGHAM HOSPITALS

IT has been shown that, even after synthesis of thyroid hormone has been prevented by the administration of thiouracil, the thyroid gland of the rat can still concentrate iodine (Taurog et al. 1947, Vanderlaan and Vanderlaan 1947). Under these conditions the iodine is concentrated as iodide, the amount contained by the gland at any given moment being proportional to the plasma-iodide level at that time. Between the thyroid gland and the plasma there is a gradient for iodide which remains constant over a wide range of plasma-iodide levels.

Stanley and Astwood (1948), producing evidence that the same holds true for man, have suggested that the amount of radioactive iodine accumulated by the thyroid gland after a dose of the antithyroid drug 2-mercapto-imidazole might be used as a measure of thyroid activity. Foss and Herbert (1952), using a modification of Stanley and Astwood's technique, found it, as a test for thyrotoxicosis, as useful as the thyroid iodide clearance.

Childs et al. (1950), investigating in man the effect of increasing amounts of inert iodide "carrier" on the behaviour of a tracer dose of radioactive iodine, showed that amounts of about 5–10 mg. of sodium iodide modified the uptake of radio-iodine by the thyroid gland in a similar way to thiouracil. The radio-iodine, being accumulated in the form of iodide, could be almost completely discharged from the thyroid gland by a dose of sodium thiocyanate. Sodium iodide in doses of this order appears to inhibit the binding of iodine to protein without saturating the iodide-concentrating mechanism of the gland.

This paper sets out the result of 86 tests done by a method similar to that of Stanley and Astwood.

METHOD

86 subjects were tested in two groups. The first group totalled 32 and comprised 12 normal volunteers between the ages of twenty and sixty-five with no history or evidence of thyroid disease, 7 patients with clinical thyrotoxicosis, and 13 patients referred for testing as possible cases of thyrotoxicosis. To these methylthiouracil 400 mg. was given by mouth four hours or more after their last preceding meal, followed an hour later by an oral dose of 35 μC of carrier-free radio-iodine.

The second group totalled 54 cases and comprised 10 normal people, 12 patients with thyrotoxicosis, and 32 patients referred for diagnosis. To these the tracer dose of 35 μC of radio-iodine was given intravenously together with 10 mg. of sodium iodide in a volume of 2 ml.

After the tracer dose counting-rates over the neck and thigh were followed until the highest count was reached, and usually for longer.

The neck was counted at a fixed distance of 20 cm. from the skin over the cricoid cartilage to the central wire of a G10 Pb counter (20th Century Electronics Ltd.) enclosed in a lead collimator 2 cm. in effective thickness. A window with an aperture 6×11 cm. at a distance of 6 cm. from the central wire exposed the whole length of the cathode to gamma rays.

The patients were seated on a chair of adjustable height in front of a lead screen 1·5 cm. thick. The counter "viewed" the neck through an opening 15×11 cm. in the screen below a rest on which the chin was placed.

Thigh counts were made with the same counter placed on a shelf 45 cm. from the ground so that the person could sit with the legs together and the outer side of one thigh pressed with its mid-point against the centre of the counter window.

RESULTS

Typical counts over neck and thigh are shown for one normal and one thyrotoxic subject from the first group in fig. 1. The counting-rates reach a maximum within two or three hours, after which, in these two cases, sodium thiocyanate 1 g. was given intravenously to discharge radio-iodine from the thyroid gland. The fall in counting-rate over the neck and the radioactivity remaining give some indication of the extent to which binding of the tracer dose to protein has taken place. Part of the counting-rate over the neck is due to radio-iodine in tissues other than the thyroid gland. The neck count falls sharply after a dose of thiocyanate, and in the thyrotoxic patient is accompanied by a rise in the thigh count which is due to the discharge

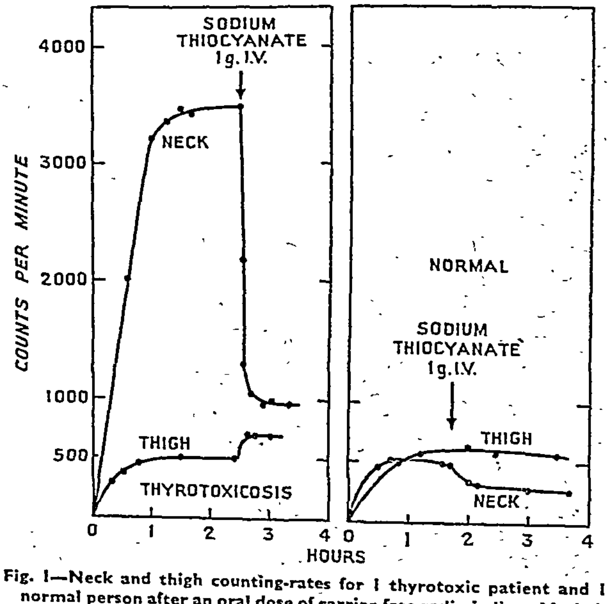

Fig. 1—Neck and thigh counting-rates for 1 thyrotoxic patient and 1 normal person after an oral dose of carrier-free radio-iodine. Methylthiouracil 400 mg. was given an hour beforehand in each case.

of a considerable amount of radio-iodine from the thyroid into the blood-stream. The amount of radio-iodine discharged from the normal thyroid gland is too small to affect the thigh count appreciably.

In fig. 2 the corresponding curves obtained after an intravenous dose of radio-iodine and sodium iodide are shown for one patient in the second group with mild thyrotoxicosis. The counting-rate over the neck reaches a maximum within twenty minutes, after which time there is a steady fall in neck and thigh counting-rates. In most of the normal people tested the counting-rate over the neck reached a maximum within a few minutes.

In view of the finding of Taurog et al. (1947) that the amount of iodide concentrated by the thyroid gland depends on the amount in the blood at any given time, it seemed desirable to express the thyroid uptake of radio-iodine in terms of the blood-iodide level measured at the same time. Childs et al. (1950) have suggested the use of the following fraction:

$$\frac{\text{Percentage of dose taken up by thyroid}}{\text{Percentage of dose per litre of plasma}}$$

This they term the "thyroid iodide space," to express the iodide uptake of the "blocked" thyroid gland. The measurement of the fraction of the dose taken up by the thyroid gland involves the use of corrections for backscatter, &c., and makes the method unnecessarily complicated. The use of the ratio of neck count to thigh count at a chosen time avoids the need for those corrections and for a plasma sample and gives an index of thyroid activity which correlates well with the thyroid iodide space. In 28 cases both indices were measured and the coefficient of correlation was found to be 0·98 (fig. 3).

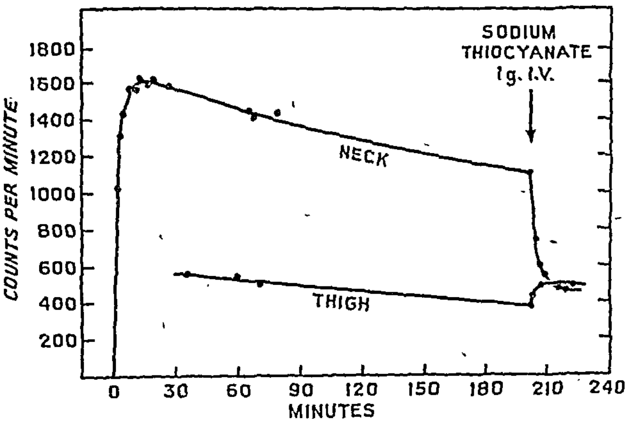

Fig. 2—Neck and thigh counts after intravenous injection of radio-iodine with 10 mg. of sodium iodide as "carrier" in mild thyrotoxicosis.

In people given an oral dose of tracer the ratio was measured after the highest thigh count had been reached and the blood and tissue levels of radioactivity were more closely in equilibrium than during the phase of rapid increase of counting-rates. After this time the thigh counts can be shown to reflect more faithfully the radioactivity of the plasma.

In the remaining cases in which the dose was given by intravenous injection, the neck/thigh ratio was always measured after thirty minutes because the neck count had reached its highest by then. The diffusion of radio-iodine into the thigh tissues is not yet complete by this time, but the choice of a constant time-interval allows a constant relation between the thigh count and blood level of radio-iodine to be assumed, although this is only strictly true if the rate of diffusion of radio-iodine is the same in different people.

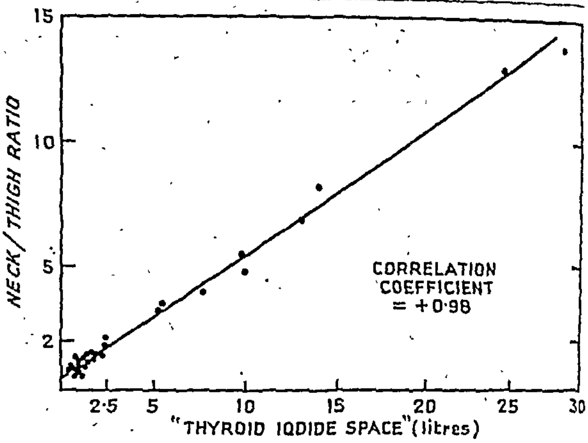

Fig. 3—Correlation between neck/thigh ratio and "thyroid iodide space" in 28 cases.

The 12 normal people in the first group gave neck/thigh ratios of 0·78–1·88 (mean 1·13, S.E. 0·09), and the 10 normal people in the second group had ratios of 0·9–1·8 (mean 1·3, S.E. 0·08). For these two series $t = 1{\cdot}29$, which gives a probability of more than 20% that the difference between the two is a chance one. It has been assumed that there is no significant difference between the two groups, and all the results have been considered together.

In 19 clinically thyrotoxic patients the ratios lay between 2·7 and 26·0, and the remaining 45, for whom the diagnosis was not definite, had ratios of between 0·8 and 4·4. These results are shown in fig. 4. It will be noted that the normals are separated by an interval from the cases of thyrotoxicosis; but, as would be expected, the patients referred for diagnostic testing overlapped both ranges.

These cases were, so far as possible, diagnosed as thyrotoxic or euthyroid without reference to the radio-iodine test, this diagnosis being indicated in the figure. The diagnosis was based on clinical assessment, sleeping pulse, basal metabolic rate, and, in some cases, response to treatment. It will be seen that, with one exception, all the cases with neck/thigh ratios of less than 1·9 were judged on other grounds than the radio-iodine test to be euthyroid. All those with ratios greater than 2·2 were similarly judged to be thyrotoxic. In 8 cases the ratios lay between 1·9 and 2·2; 3 of these patients were considered on clinical grounds to be euthyroid and 5 mildly thyrotoxic.

The single exception was a woman, aged 62, with a neck/thigh ratio of 1·4. She showed many features

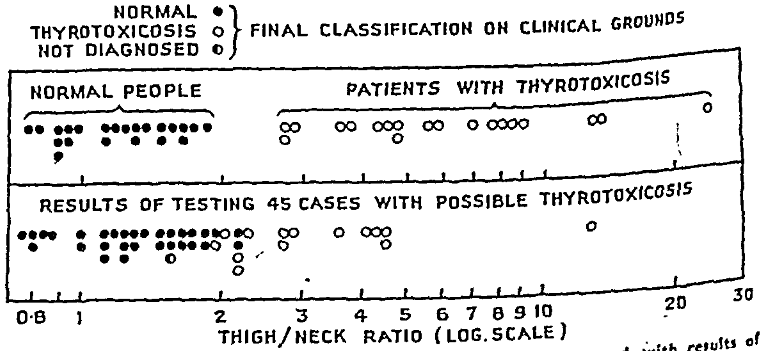

Fig. 4—Neck/thigh ratio in normal and thyrotoxic people compared with results of tests on 45 cases referred for diagnosis. Clinical diagnosis is indicated in each case.

suggesting thyrotoxicosis but also had mild rheumatoid arthritis. Treatment with thiouracil was refused, and no final diagnosis was reached.

DISCUSSION

The only figures for this kind of test so far available are those of Foss and Herbert (1952), and further results are needed to compare its value with that of the more usual "unblocked" tests of thyroid activity. While it was not practicable to make this comparison by carrying out several different tests in every case investigated, in 3 cases measurements of thyroid iodide clearance were also made by the method of Myant et al. (1949):

The first patient had an anxiety state, and gave normal results to both tests, having a neck/thigh ratio of 1·6 and a thyroid iodide clearance of 45 ml. per minute.

The second was judged clinically, and by her subsequent response to thiouracil, to have mild thyrotoxicosis. Both tests gave intermediate results—a neck/thigh ratio of 2·1 and a clearance of 75 ml. per minute.

The third had ophthalmopathic Graves's disease with a normal clearance of 35 ml. per minute and, two days later, a definitely raised neck/thigh ratio of 3·2. This patient had taken several doses of an expectorant medicine during the previous four days, each dose containing about 0·3 g. of potassium iodide, and this explains the apparent disagreement between the two results, the blocked uptake test being much less likely to be falsified by an increase in iodine intake than the thyroid iodide clearance.

The fact that this test remains relatively unaffected by large increases in iodine intake is its main advantage. Foote and Maclagan (1951), using an "unblocked" radio-iodine test in 100 subjects, mention that falsely low results were obtained in 3 cases as the result of high iodine intake. A dose of about 10 mg. of sodium iodide administered with the tracer dose will greatly modify protein binding and therefore give misleading values for thyroid iodide clearance but will not affect the "blocked" uptake.

A further advantage is that the greater part of the radio-iodine taken up by the thyroid gland leaves it within twenty-four hours, thus subjecting it to less radiation than it would receive if protein binding were allowed to occur.

Sources of inaccuracy in this type of measurement have been discussed by Foote and Maclagan (1951); but, besides those which they mention, two further errors may be introduced by using a "blocking" agent. Firstly, some of the radio-iodine is bound to protein, in spite of the use of methylthiouracil or sodium iodide. This finding, which varies from patient to patient, causes the amount of radio-iodine in the thyroid gland to be overestimated to some extent. To allow for this by measuring the residual radioactivity in the neck twenty-four hours after the dose would complicate the test unduly and require the assumption that this radio-iodine had all become protein-bound by the time of the measurements on the previous day.

In this connection it is worth noting that the neck/thigh ratio of the case shown in fig. 2 is 2·7 at 30 minutes, and 2·8 if measured at 180 minutes, after the intravenous injection. In this case very little protein binding of radio-iodine has taken place, but in other cases in which it has not been so effectively prevented the ratio will be found to increase with time, since the protein-bound radio-iodine does not leave the gland as the blood level of radio-iodine falls. For this reason it is desirable to measure the ratio as early as possible after the highest counting-rate has been reached, so as to diminish the error introduced by protein binding.

Accuracy of measurement is also affected by the fact that "blocking" the thyroid gland diminishes the uptake of radio-iodine considerably. Thirty minutes after an intravenous injection of radio-iodine the "blocked" uptake is about half as much as the "unblocked" uptake and correspondingly lower in comparison with the radioactive background provided by the other tissues of the neck, which fact must to some extent diminish the accuracy of measurement. Unlike the "unblocked" uptake of radio-iodine, the radioactivity in the thyroid gland falls in parallel with that in the other neck tissues, and accuracy cannot be increased by delaying measurements until tissue radioactivity has fallen to a low level.

Values found for the "thyroid iodide space" in 10 normal people varied between 0·5 and 2·4 litres, with a mean of 1·26 litres. Assuming the normal thyroid gland to weigh 25 g. it appears to concentrate iodide about fiftyfold, when 1 g. of thyroid tissue is compared with 1 ml. of plasma. In 5 thyrotoxic patients the weight of the thyroid gland was estimated from the weight of tissue removed at operation. By using this and the previously measured values for the "thyroid iodide space" figures for iodide-concentrating power were obtained which varied between 120 and 325 times. Vanderlaan and Vanderlaan (1947) obtained values of 25–50 times for the normal rat thyroid gland and about 250 times when the gland was made hyperplastic by prolonged treatment with propylthiouracil.

There is evidence that iodide-trapping takes place to the same extent in the "unblocked" thyroid gland, merely being thrown into prominence by the use of drugs such as thiouracil which prevent this function from being overshadowed by that of hormone synthesis. Lein (1943) showed in rabbits that the radio-iodide content of the thyroid gland rose rapidly to a peak ten minutes after an intravenous injection of radio-iodine and thereafter slowly fell. The protein-bound (acetone-insoluble) radio-iodine continued to rise steadily for some hours. Franklin et al. (1944) found that slices of sheep's thyroid contained similar quantities of inorganic iodide whether protein-binding was prevented by thiouracil or allowed to take place freely. In some people it appears that protein binding may be blocked spontaneously. Stanbury and Hedge (1950) describe several cretins with large goitres in whom the iodide-concentrating mechanism was intact but not the ability to bind iodine to protein and thus synthesise thyroid hormone.

It will be seen that the measurement of the neck/thigh counting-ratio an hour after an intravenous injection of carrier-free radio-iodine, as suggested by Pochin (1950), is probably to some extent a measure of iodide accumulation. At this time about a third of the radio-iodine in the thyroid gland is likely to be in the form of iodide, although the relative proportions of iodide and protein-bound iodine may not remain the same in glands of differing activity. The present results do not indicate whether the advantages gained by preventing protein binding of iodine are outweighed by the fact that the binding is not completely arrested but is still able to take place to a variable extent.

SUMMARY

The uptake of an oral dose of radioactive iodine by the thyroid gland was measured in 32 people after a dose of 400 mg. of methylthiouracil. To a further 54 people the radio-iodine was given intravenously together with 10 mg. of sodium iodide. Using either method the radio-iodine was accumulated mainly in the form of iodide and was not fixed by the gland.

The two methods appear to give equivalent results, but the second is more rapidly completed, the concentration of radio-iodine by the thyroid gland reaching a maximum within twenty minutes of an intravenous injection.

The ratio of the counting-rate over the neck to that registered over the thigh was used as an index of the iodide-concentrating power of the thyroid. By using this ratio it was possible to make a definite diagnosis in 38 out of 46 cases referred for diagnostic testing.

This test is rapidly completed, is unlikely to be affected by variation in dietary iodine, and subjects the thyroid gland to less radiation than do methods using "unblocked" uptake.

I wish to thank Prof. W. M. Arnott for his encouragement and advice, and the physicians of the United Birmingham Hospitals for access to their patients. Some of the work in this paper has previously been submitted as part of a thesis for the degree of M.D. of the University of Cambridge.

SUCCINYLCHOLINE IN THE TREATMENT OF TETANUS

RONALD WOOLMER

SENIOR LECTURER IN ANÆSTHETICS IN THE UNIVERSITY OF BRISTOL

J. E. CATES
M.D. Lond., M.R.C.P.
LECTURER IN MEDICINE IN THE UNIVERSITY

IN tetanus the well-known dangers of exhaustion, dehydration, and infection of the lungs are largely consequences of the muscle rigidity and spasms. The use of hypnotic drugs to lessen muscle spasm increases the danger of respiratory infection. The peripherally acting muscle relaxants therefore promised to be of value in treating tetanus. Since West (1936) described the benefit of curare this drug has often been used (Cole 1951, Frank 1951); and more recently cases have been treated with other muscle relaxants, such as mephenesin (Boles and Smith 1951, Bandi 1951, Davison 1951, Godman 1951, Nilsson 1950, Newhouse et al. 1950, Belfrage 1947) and decamethonium (Keir 1950). These three drugs, however, act comparatively slowly; they cannot follow the rapid fluctuations in muscle tone which are characteristic of tetanus. With succinylcholine, on the other hand, the degree of muscle relaxation can be varied widely in a matter of seconds, and the dose can be continuously adapted to the requirement of the moment.

This paper records experience with a continuous infusion of succinylcholine for three and a half days in a patient with tetanus.

CASE-RECORD

A spinster, aged 58, underwent an operation for removal of nasal polypi on June 3, 1952. No catgut was used, and the postoperative course was uneventful except for slight but persistent bloodstained nasal discharge. During the week June 22–29 the patient toured Scotland by motor coach and at times she was driven through clouds of road dust. On July 4 her jaws became painful and stiff and she had difficulty in chewing her food and in swallowing. Next day she could not open her mouth or swallow her saliva; her neck and shoulders became stiff and painful. She was admitted to hospital on the night of July 7.

On examination on July 8 there were an obvious risus sardonicus and trismus—she could separate her teeth by about $^1/_8$ inch. There was continuous rigidity of the neck and upper back muscles; the abdominal muscles were becoming firm, and all tendon-jerks were grossly exaggerated. There was no cranial nerve paralysis. An attempt to examine her mouth caused a severe spasm, which involved the larynx as well as the neck and shoulder muscles, and the patient became deeply cyanosed and lost consciousness for about a minute. No wound was found, and no sepsis was discovered at the site of the nasal operation. Swabs from the nose grew *Staphylococcus aureus* but no *Clostridium tetani*.

Treatment.—Antitetanic serum 100,000 units was given intramuscularly and repeated three days later; procaine penicillin ('Distaquaine') 900,000 units was given daily for ten days. A Ryle's tube could not be passed, the attempt causing an alarmingly prolonged spasm. It was decided to postpone tracheotomy until the effect of succinylcholine was seen.

Effect of Succinylcholine.—The patient's response to succinylcholine was first assessed by intravenous injections of different doses. 10 mg. caused complete flaccidity for about three minutes and necessitated artificial respiration with oxygen. Two doses of 2·5 mg. two minutes apart caused decrease in respiratory excursion without abolishing trismus. On these findings the patient was given an intravenous drip of isotonic saline solution containing 3 mg. per ml., the rate being varied to deliver between 1·5 and 3 mg. per minute. On this régime the patient was more comfortable and free from major spasms for several hours, but she could not swallow or clear her throat. When the drip was discontinued, a severe spasm with cyanosis developed in three or four minutes. By making minor alterations in the rate of infusion it was possible to steer the patient between mild overdosage (diplopia, shallow respiration with cyanosis) and underdosage (painful spasms of the neck and back, together with laryngeal spasms).

July 9.—During the day the patient became worse and the laryngeal spasms could not be controlled without causing so much respiratory paralysis that there was cyanosis. The dosage of succinylcholine needed to produce this flaccidity was between 1·0 and 1·5 mg. per minute. The patient was also becoming embarrassed by retained material in her pharynx; so tracheotomy was done under local anæsthesia. Thereafter the trachea and posterior nasal space were sucked out at short intervals. This procedure naturally caused laryngeal and generalised spasms; but these could be prevented, or rapidly abolished, by boosting the dosage of succinylcholine so that 5 or 10 mg. was given in a few seconds; during the resulting paralysis the patient could be sustained by inflating the lungs with oxygen through the tracheotomy tube.

July 10.—It was again possible to steer the patient between paralysis and spasms for most of this day; but this entailed almost constant medical supervision. At times it was necessary to give oxygen by artificial respiration; only light pressure on the oxygen bag was needed. The patient however, had slept very little. She was becoming exhausted and her pulse-rate was rising steadily. After 16 ml. of paraldehyde in oil per rectum at 11 P.M. she slept. Succinylcholine had to be given continuously, otherwise painful spasms occurred and woke the patient. The optimal dosage fell so that by 2 A.M. only 0·2 mg. per minute was required; with this dose respirations were so shallow that continuous oxygen was needed to prevent cyanosis.

July 11.—After about eight hours' almost uninterrupted sleep the patient woke refreshed. Succinylcholine was stopped for five hours, except for short periods to cover aspiration of the trachea and pharynx. During most of this time spasms occurred every five to fifteen minutes; during these bouts the patient became cyanosed and needed oxygen for a few minutes after each. For these reasons the succinylcholine drip was started again at 1.30 P.M. and was given for another eight hours, after which it was finally discontinued. The patient was given 16 ml. of paraldehyde rectally and slept in snatches afterwards.

July 12.—The spasms became less frequent, about one every hour; and they were less severe, causing little cyanosis. Improvement thereafter was gradual.

Progress.—Spasms stopped on July 16; rigidity went more slowly; and stiffness of the jaws persisted until July 25. Some lumbar œdema and basal râles were present on July 12, and remained for a week.

The intravenous fluids given during the first five days were equivalent to $3^{1}/_{2}$ litres of isotonic glucose and $2^{1}/_{2}$ litres of isotonic saline solution.

DISCUSSION

There is little doubt that succinylcholine contributed to this patient's recovery. The continuous infusion reduced the muscle rigidity and the severity of the spasms. It would have needed large doses of hypnotic drugs to achieve equivalent relaxation. This would clearly have endangered the already embarrassed respiratory system. By increasing the rate of drip of succinylcholine the patient could be made flaccid while the nasopharynx and trachea were aspirated, while penicillin was injected, or while attention to the back or other nursing manœuvres were completed. This sometimes gravely weakened the patient's respiratory muscles, but anoxia could easily be avoided by inflating the lungs with oxygen. Likewise, the combination of paraldehyde with succinylcholine, continuous oxygen, and, when need be, artificial respiration seemed to be of decisive value when the patient needed sleep during the critical stage of her illness.

Though the use of muscle relaxants is clearly logical in tetanus it complicates the therapeutic problem. The aim is to abolish exaggerated muscle tone without seriously weakening the respiratory apparatus. Though this can be done in patients with a normal neuromuscular system it cannot always be done in patients with tetanus (Adriani and Ochsner 1947, Woolmer 1949). Even when it can be done, the dose required will vary from minute to minute. The degree of muscle tone (which is an expression of the balance between acetylcholine and cholinesterase) depends on many factors. The most important of these are sensory stimuli and tetanus toxin, which increase it, and sedatives and antitoxin, which decrease it. Since these factors vary widely, muscle tone cannot be expected to remain constant, and therefore the dose of relaxant that is right at one moment will at the next be either insufficient to prevent spasms or enough to cause respiratory paralysis. If complete control is the aim—and by this is meant the achievement of a *continuous* balance between muscular relaxation and respiratory paralysis—it is clearly an advantage to use a method, such as continuous succinylcholine, which is capable of minute-to-minute adjustment.

The variation in required dosage was well illustrated in this patient. At first 2·5 mg. a minute caused some relaxation without affecting breathing; later 0·2 mg. a minute caused decreased respiration and cyanosis. The change was presumably due to the fact that, as time went on, more toxin was being neutralised by antitoxin, and the acetylcholine-cholinesterase balance was moving in the direction of decreasing muscle tone. It is also possible that some cumulative action was being exerted by the succinylcholine. Serum-cholinesterase estimations might be of interest in future cases (Evans et al. 1952).

Because of the flexibility of the method, a nearer approach to complete control was attained in this case than in any other in our experience. In practice, however, the need to vary the dosage and the need to give oxygen with artificial respiration mean that this form of treatment entails virtually continuous medical attention, day and night, for several days.

SUMMARY

Succinylcholine was given for three and a half days by continuous intravenous drip to a patient with tetanus.

Administration needed practically constant medical supervision.

Succinylcholine given in this way seemed to be a valuable contribution to recovery.

Our thanks are due to Mr. Angell James for doing the tracheotomy.

FATAL POISONING IN CHILDREN FROM ASPIRIN, QUININE, AND ANTHISAN

D. A. SLADE
M.R.C.S.

CONSULTANT PATHOLOGIST, COUNTY HOSPITAL, YORK

OWING to the comparative rarity of accidental poisoning in children, the following three separate cases may be considered of interest.

ASPIRIN POISONING

Case 1.—A girl, aged 1 year 6 months, healthy and active, was found by her mother playing with an aspirin bottle a quarter full of tablets, there being pieces of tablets on the floor. This bottle was usually kept in a drawer within reach of the girl. The child seemed quite well and remained so until she went to bed at 6 P.M. At 10.30 P.M. the mother woke up and gave her some milk and water and, thinking she was cold, took her into bed, when she was sick. Her cot was brought into the mother's room, and the child went to sleep again. At 3 A.M. next morning she was sleeping peacefully, but at 8 A.M. the mother found her with blue lips and no sign of life and sent for the doctor, who found the child was dead.

Necropsy findings 33 hours after death. The cerebral vessels were congested. The stomach contained only a small quantity of thin yellow fluid, and the mucosa was sodden and intensely congested in places. The thymus was congested, with many small petechial hæmorrhages. The lungs were deeply congested with blood. The heart was congested, with subpericardial petechial hæmorrhages. The kidneys showed a few small subscapular hæmorrhages. The liver was yellowish brown, soft, and with large hæmorrhagic areas. The viscera contained salicylic acid, the decomposition product of aspirin; the stomach and its contents contained gr. $^{1}/_{20}$, and the liver gr. $1^{1}/_{10}$. From these figures it was calculated that about eight tablets, each of gr. 5, had been consumed.

At no time after playing with the bottle of aspirin tablets was the girl seen to perspire or to be flushed. About 7 hours elapsed before she vomited. Death occurred suddenly, about 15 hours after ingestion, possibly in a convulsion; no early signs or symptoms of aspirin poisoning were noted by the mother. In adults death has followed the taking of gr. 150, but a more usual fatal dose is gr. 300–450. Calculated from the smallest recorded fatal dose the equivalent for a child of the patient's age would be gr. 20; but it was estimated that she had taken gr. 40.

QUININE POISONING

Case 2.—A healthy and active girl, aged 1 year 9 months, was seen to swallow a pill at 10.30 A.M. Her mother therefore gave her a dose of syrup of figs. The child did not vomit, and half an hour later the doctor could find nothing wrong with the child and prescribed syrupus ipecacuanhæ. At 12.45 P.M. the child died in convulsions.

Necropsy findings 26 hours after death. The face was cyanosed, and the cerebral vessels were intensely congested. The stomach and small intestine contained a little thick and slightly blue matter. The lungs were intensely congested with blood and rather œdematous. The right auricle and ventricle were congested. The viscera contained a con-

siderable quantity of quinine sulphate and iron. The stomach and its contents contained gr. 3 of quinine sulphate together with three undecomposed pills. The liver contained gr. $^3/_4$ of quinine sulphate, and the urine gr. $^1/_{40}$ of quinine sulphate. The pills were of iron and quinine, containing gr. $^1/_5$ of quinine sulphate. They did not contain any strychnine.

Before general protoplasmic poisoning sets in, there is a preliminary short stage of excitation, and convulsions may develop. The quinine alkaloids cinchonine and cinchonidine present in quinine sulphate are convulsants. Quinine can be similar to strychnine in its convulsant effects. The respiratory centre is first stimulated, causing fast, shallow, inefficient respirations, and later paralysed. There is also a fall of blood-pressure and direct cardiac depression.

The maximal *B.P.* therapeutic dose of quinine sulphate for an adult is gr. 10; so that for a child aged 1 year 9 months would be gr. $1^3/_4$, which dose was greatly exceeded. Smith (1938) states that the toxic dose is difficult to estimate in adults, being recorded as between gr. 27 and gr. 240. The proportionate toxic dose for a child aged 1 year 9 months would be gr. 3–4. More than this was found in the child's body. Sollmann (1949) states that in an adult recovery has followed the taking of gr. 450. Fatal cases in children are uncommon. Bamford (1947) states: "Children have been fatally poisoned by swallowing tablets." Willimott (1931) reported a case of fatal poisoning in a child, aged $2^1/_2$ years, following ingestion of 26 tablets, each of gr. 5. Nelson (1950) describes the premonitory symptoms preceding coma and death but does not say what is a fatal dose.

ANTHISAN POISONING

Case 3.—A healthy and active girl, aged 1 year 4 months, was found at noon putting her hand to her mouth, with a small white box, which contained tablets of 'Anthisan' (pyranisamine maleate), lying open on the floor. This box had been in a drawer 2 ft. above the ground. Soon afterwards the child began retching, but only vomited a little after some warm tea had been given. Her colour was good, and she was put in a chair but fell off in a convulsion, the time of onset of which was not noted. Before leaving for hospital at 1.30 P.M. the child was almost certainly dead, being very white and still. Death was certified at 1.50 P.M.

Necropsy findings 21 hours after death. The cerebral vessels were congested. The stomach contained a little mucoid material with flecks of blood. The blood-vessels were congested, as were the intestines. There was thick bluish-green fluid in the small intestine. The larynx, trachea, and bronchi were clear and pale, and their inner surface was covered with thin watery fluid. The lungs were acutely emphysematous and congested. The left ventricle appeared to be in systolic contraction.

Histology.—The only organs to show any changes of note were the lungs, where there was congestion of the capillaries with irregularly loculated areas of collapse, associated with interstitial and intra-alveolar œdema. The stomach contents contained gr. $^1/_{14}$ of anthisan, the contents of the small intestine gr. $^1/_4$, and the liver gr. $^1/_2$.

Each tablet contained about gr. $1^1/_2$ of anthisan equivalent to about gr. $1^1/_4$ of pyranisamine. Hence the child had consumed up to six anthisan tablets. Such a dose would undoubtedly be fatal in a small child.

Possibly the toxic effect of the quinidine-like action on the heart caused the fatal convulsion by producing heart-block, ventricular fibrillation, or inhibition of the whole heart (Sollmann 1949).

Few deaths have been reported in children, and the smallest fatal dose in children is not established.

COMMENTS

These three cases bear similarities, although the drugs were so different, in that the children were healthy, were of similar ages, and had found the tablets which were put away within their reach.

In cases 1 and 2 there were no immediate symptoms and it was uncertain whether the tablets had been consumed, but in case 3 symptoms came on quickly, the child being seen putting tablets in her mouth. Death took place suddenly in each case, in convulsions with anthisan and quinine and possibly so with aspirin.

Absorption was probably hastened in case 2 by syrup of figs and in case 3 by warm tea.

When there is a strong possibility without definite evidence that a child has swallowed possibly poisonous tablets, it should be assumed that this has happened, rapid action should be taken to empty the stomach, and nothing should be given by mouth that could hasten absorption.

I wish to thank Colonel E. Laverack, H.M. coroner for the Howdenshire district; Mr. E. T. Heap, H.M. coroner for the West Riding; and Colonel I. N. Ware, O.B.E., H.M. coroner for York for allowing me to make extracts from their depositions in these cases. I am also grateful to Mr. L. C. Nicholls, director of the Metropolitan Police Laboratory, for the chemical analyses.

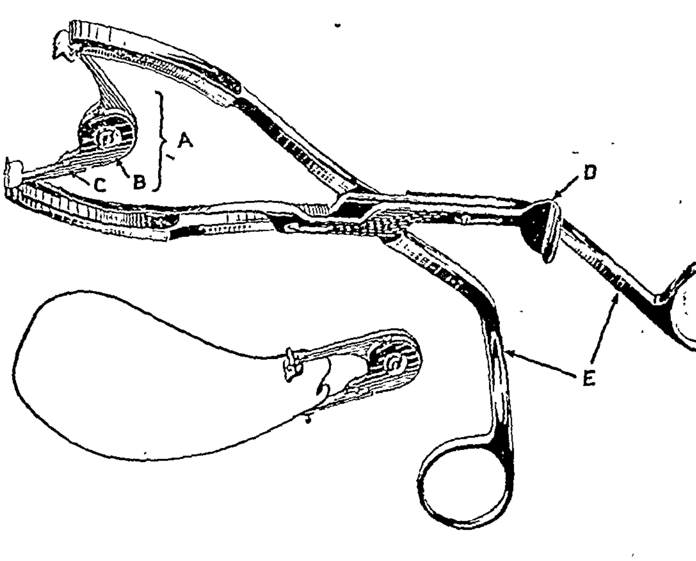
New Inventions

A CERVICAL OCCLUSIVE CLAMP

As a preliminary to total hysterectomy for carcinoma of the body of the uterus, it is an agreed and logical practice to occlude the cervix by some means in order to prevent malignant cells escaping during the operation. The relative frequency with which the growth recurs in the vault makes this procedure rational, and encourages the use of any simple measure which will limit local recurrence even further.

Such measures as packing the uterus with spirit or formalin-saline solution have been used either alone or combined with suturing of the cervix. This by no means produces a watertight or cell-tight seal, and, since this type of growth is commoner in nulliparous women, it is often very difficult to suture the cervix perfectly.

The purpose of this clamp is to occlude the cervix more tightly than has been found possible by any other means. Its efficiency has been tested extensively in



benign cases by filling the uterus with indigo-carmine solution before total hysterectomy; there has never been any escape of fluid.

In the accompanying figure, the clamp unit (A) consists of sharp toothed upper and lower jaws, supported by strong arms converging at a hinge $1\frac{1}{2}$ in. distant; the opening and closing of the jaws is controlled by a rachet mechanism (B) neatly located in the hinge. The control lever (C) of the rachet lies parallel to the arm of the lower jaw, where it may be disengaged readily by a simple device (D) on the carrier forceps (E) when the clamp is approaching the cervix in the vagina. This allows the clamp to be introduced in the closed position through the narrow introitus of the nulliparous patient, and then to be opened when the roomier vagina is reached so that it can grip and compress the cervix. Immediately before the final compression of the cervix, the rachet on the clamp is allowed to come into action merely by operating the disengaging lever (D) on the carrier forceps. Full compression is thus securely maintained. The carrier forceps are then easily slipped off the clamp by a slight opening movement of the handles.

The clamp, which is made in two sizes (standard and large), takes up very little room in the vault and in no way interferes with the hysterectomy. In fact it acts as a very convenient landmark which identifies the base of the portio vaginalis. The clamp and carrier forceps are easily dismantled for cleaning.

This clamp should be capable of modification to suit temporary occlusive procedures in other operative fields.

The instrument may be obtained from Heaton Grogan Co. Ltd., 21, Bowling Green Lane, Clerkenwell, London, E.C.1, to whom much credit is due for its final production.

Reviews of Books

Non-Pulmonary Tuberculosis of Bovine Origin in Great Britain and Northern Ireland

GRAHAM SELBY WILSON, M.D., F.R.C.P., D.P.H., director, public health laboratory service, Medical Research Council; J. W. S. BLACKLOCK, M.D., F.R.F.P.S., professor in pathology, St. Bartholomew's Hospital Medical College, London; LILIAN VIOLET REILLY, B.SC., M.D., D.P.H., bacteriologist, Northern Ireland Tuberculosis Authority. London: National Association for the Prevention of Tuberculosis. 1952. Pp. 108. 16s.

IN this volume three papers dealing with findings for England and Wales, Scotland, and Northern Ireland have been brought together, and a general discussion of the English and Welsh and the Scottish reports has been added. The distribution of human and bovine bacilli is analysed in detail according to types of disease, age of patient, contact history, milk-drinking history, and region of domicile of patient. The calculation that in Great Britain as a whole in 1944 there were 1600 deaths from non-pulmonary tuberculosis due to bovine-type bacilli has already had the full publicity it deserves. This volume contains the evidence needed to demand that all milk for human consumption should be made safe by efficient heat treatment, unless it is known to be derived solely from a herd of non-reactors to tuberculin. The evidence that the number of such herds should be increased as rapidly as possible is equally strong.

The Metabolic Response to Surgery

FRANCIS D. MOORE, M.D., Moseley professor of surgery, Harvard Medical School, Boston, Mass., and MARGARET R. BALL, A.B. Metabolic diagrams by MILDRED B. CODDING, A.B., M.A. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 156. 55s.

To show how the human body responds to injury, Professor Moore and his team have arranged the results of some of the metabolic balance studies they have made during the last six years. The effects of surgical operations of varying severity in different types of patient, and of starvation, immobilisation, and changes in endocrine secretion, on nitrogen, sodium, and potassium metabolism, are discussed and evaluated.

The writers illustrate the disturbances associated with multiple operations and with large extrarenal losses of body-fluids accompanying intestinal fistulæ, and the changes associated with burns and bilateral adrenalectomy. They also discuss how much the normal effects of injury can, or should, be disturbed by treatment, giving case-histories (which are an important part of the book) and describing the value of protein supplements such as albumin, whole plasma, and solutions containing amino-acids or protein hydrolysates. The importance of adequate provision of calories with amino-acid and hydrolysate preparations, and the slow rate of turnover of albumin and whole plasma, are emphasised. They mention the difficulty of interpreting metabolic balance studies in which materials are pooled for periods of three, four, or even seven days. Difficulty also arises when the preoperative period of study is too short for the existing plane of metabolism of the patient to be assessed. The last chapter summarises the evidence and recommendations, and a useful appendix gives the detailed composition of diets and intravenous infusions suitable for the various stages of treatment.

Here is described in detail the stuff the sick are made of. The essential normality of the metabolic changes after injury is emphasised and enthusiastic claims to have reversed such reactions, by overwhelming the urea ammonia mechanism with hydrolysed protein, are disarmingly discounted. This book should have a profound effect on the postoperative treatment of all patients and especially those whose convalescence is complicated by infection, wound disruption, or leakage from fistulæ.

Understanding Heredity

An Introduction to Genetics. R. B. GOLDSCHMIDT, professor emeritus of zoology, University of California. New York: John Wiley. London: Chapman & Hall. 1952. Pp. 228. 30s.

ENCOURAGED by the public interest in the Lysenko controversy, Professor Goldschmidt has written a book setting out clearly and simply the principles of genetics. He does not directly refute Lysenko's views: but he shows that the main outline of mendelian segregation fits so well with the observed behaviour of the chromosomes that the reader will be convinced that the chromosomes are the main bearers of heredity. The later chapters, covering more difficult topics—gene collaboration, multifactorial inheritance, multiple alleles, and physiological and biochemical genetics—are well written but less convincing. Here the reader without special knowledge of genetics must take Professor Goldschmidt on trust as a reliable guide. Medical practitioners will be pleased to note his full account of mutations; many doctors find it difficult to appreciate that where a condition seriously affects health, even though it is determined by a single dominant hereditary factor, most patients will have a "negative family history."

Isotopes in Biochemistry

Ciba Foundation Conference. Consulting editors: J. N. DAVIDSON, M.D., L. H. GRAY, PH.D., A. S. MCFARLANE, M.B., A. NEUBERGER, M.D., F.R.S., G. POPJÁK, M.D., and C. RIMINGTON, PH.D. Editor for the Ciba Foundation: G. E. W. WOLSTENHOLME, M.B. London: J. & A. Churchill. 1951. Pp. 288. 27s. 6*d*.

AN informal international meeting of workers with isotopes in the biochemical field was held in London in March, 1951, under the auspices of the Ciba Foundation. The proceedings, consisting in communications followed by discussions, are published with a foreword by Sir Charles Harington, F.R.S. The speakers were concerned on the whole less with technique than with the results obtained with isotopes in various branches of biochemistry, but the extent to which procedures such as chromatography, ionophoresis, and infra-red spectrometry are being used in isotope work clearly emerges. Six fields were covered: steroids; hæmoglobin and metabolic derivatives; the use of tracers in the study of biological effects of radiation; nucleic acids; proteins and amino-acids; and carbohydrate and fatty acid metabolism. All the subjects discussed had an indirect, and some also a direct, reference to medicine.

C. P. Leblond emphasised the excretion of steroids in the bile, and K. Bernhard, after studying a spleen of high cholesterol content in a case of splenic tumour, suggested that cholesterol is synthesised by this organ. A. Neuberger pointed to discrepancies between the isotopic and agglutination methods of measuring the life span of the human red cell; the hæmoglobin may not be so completely locked up in the cell as was thought. A. Hollaender, G. E. Stapleton, and W. T. Burnett reported that *Bacterium coli* is protected from X-ray damage by a variety of compounds, especially thiols and carboxylic acids. E. Hammersten's findings indicate that synthesis of nucleoproteins precedes, and is necessary for, synthesis of proteins. From studies of fatty acid synthesis in the mammary gland, G. Popják concluded that it proceeds by stepwise addition of two-carbon units, and suggested that the glycerol supply may sometimes be rate-limiting in fat synthesis. In the discussion S. Gurin stressed pituitary-pancreas antagonism in fat synthesis from acetate.

Sodium Metabolism in Health and Disease

DOUGLAS A. K. BLACK, M.D., F.R.C.P., lecturer in medicine, University of Manchester. Oxford: Blackwell Scientific Publications. 1952. Pp. 79. 9*s*. 6*d*.

OUR knowledge of the physiology and the functional pathology of the electrolytes in man is advancing so rapidly that few who are not working in this field can keep pace. Many of the published reviews consist largely of diagrams and are difficult to follow or digest. This small monograph, which was awarded the Rogers prize of the University of London in 1951, reviews the highly complex problems of sodium metabolism, covering work published up to eighteen months ago. In a surprisingly small space Dr. Black covers such diverse subjects as the excretion of sodium, its distribution in the body, its metabolism in the infant, the clinical effects and treatment of sodium depletion and retention, and the rôle of the adrenal cortex. This is a really readable introduction to a difficult subject. A companion volume on potassium would be equally welcome.

Clinical Pathology of the Eye

BERNARD SAMUELS, M.D., emeritus clinical professor of ophthalmology, Cornell University Medical College; ADALBERT FUCHS, M.D., E.O. professor of ophthalmology, University of Vienna. London: Cassell. 1952. Pp. 420. £7. 7*s*.

THE opening chapter of this work deals with the general pathology of the eye, and the 7 succeeding chapters with the different ocular structures. The last 6 chapters cover myopia, tuberculosis, syphilis, post-operative pathological findings, injuries, and tumours. Unfortunately the text as a whole deals more with morbid histology than with the wider aspect of pathology, and thus fails to live up to its title. The illustrations leave nothing to be desired; but the supporting text is uneven, the technical revolution through which histology is passing at present is overlooked, the descriptions tend to be confined to individual entities, and the teaching is not always up to date. The significant work of Callendar and Wilder on the histology of choroidal melanomata is ignored in favour of a rather obsolete interpretation, and the pathology of phlyctenular ophthalmia is discussed in almost meaningless terms. Sympathetic ophthalmia is firmly, and perhaps rightly, ascribed to virus infection. The great experience of the authors in the morbid histology of the eye lends authority to many specialised accounts scattered throughout the text, but this cannot be regarded as an adequate presentation of the current teaching in ophthalmic pathology.

The Human Blood-groups

P. H. ANDRESEN, M.D., chief, municipal blood bank, Bispebjerg Hospital, Copenhagen. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 114. 25*s*. 6*d*.

THIS book deals mainly with the medicolegal applications of blood-grouping. It gives adequate detail about the distribution and heredity of the blood-groups and the application of this information in cases of disputed paternity: it also deals with the use of blood-group methods for the identification of blood stains, semen, and saliva. Actual techniques of blood-grouping are hardly mentioned at all, and the author seems satisfied with the slide method. A former chief of the serological department in the Copenhagen University Institute of Legal Medicine, Dr. Andresen has had more experience of this kind of work than anyone in Europe; in fact, only A. S. Wiener in New York has had comparable numbers to deal with. In Denmark the courts can make compulsory orders for blood-group tests in suitable cases, and at present about 2000 disputed paternity cases are settled annually. The courts, moreover, can have these tests done at the University Institute, which is not run by the police and accepts no fee from the plaintiff. Apparently the Danish Medicolegal Council still relies on the use of the ABO, A_1A_2, and MN systems. Dr. Andresen consequently gives most space to these; but he does deal quite adequately with the Rh system and the "secretor" phenomenon, and he mentions briefly the other blood factors such as P, S, and the Lewis groups. He does not commit himself on the question of the Rh group nomenclature, and it is unfortunate that apostrophes have often been substituted for dashes in the symbols of Wiener's nomenclature (e.g., Rh' for Rh′). This book, however, fills a gap in the literature and Dr. Andresen's wide experience allows him to point out the difficulties and limitations, as well as the possibilities, of blood-group techniques.

Mind: A Social Phenomenon

Illustrated by the Growth of Medical Knowledge. F. S. A. DORAN, M.A., M.D., F.R.C.S., clinical demonstrator in anatomy, University of Manchester. London: Watts. 1952. Pp. 182. 10*s*. 6*d*.

To say anything new about the mind-body problem calls for genius: even to restate the issues arrestingly demands exceptional freshness of outlook. Dr. Doran is a painstaking and thoughtful man who writes clearly, but does not manage to grapple with the complexities of his theme or the stronger arguments of the dualist. As a simple statement of the view that mind is an expression of brain function, and a rapid résumé of the history of medical thought, the book is interesting and would give a useful turn to a medical student's reflections.

Méconnaissances et hallucinations corporelles

Intégration et désintégration de la somatognosie. H. HÉCAEN and J. DE AJURIAGUERRA. Paris: Masson. 1952. Pp. 382. Fr. 2300.

THIS interesting monograph from the Paris school of neurology deals with problems common to neurology and psychiatry which have recently attracted renewed interest. The theme of the book is disturbances of the body-image; and phantom limbs, anosognosia, constructive apraxia, the Gerstmann syndrome, "hallucinations of the self," and other aspects are discussed in detail. The authors give many personal case-records with, in some cases, detailed pathological reports; and these are correlated with previous work on the subject. The production of the book is good, but the price seems high for a paper-bound volume.

Architectural Principles in Arthrodesis (2nd. ed. E. & S. Livingstone. 1952. Pp. 196. 42*s*.).—The second edition of Mr. H. A. Brittain's well-known monograph has been largely rewritten, and expanded in various ways. It is a craftsman's manual, not pretending to any wide discussion of the indications for arthrodesis as opposed to any other procedure in a given case, and it has the advantages and disadvantages of this type of book. He is a persuasive advocate of the operations he describes, many of them the result of his own original thoughts and methods. The principles he expounds so clearly are those essential for the embodiment of the graft, which he considers the mainstay of all arthrodeses. He does not attempt any wide description of other methods of arthrodesis, and the book is therefore of greater value to the surgeon of some experience than to the student.

Brittain's ischiofemoral arthrodesis has come to stay; over the last ten years the experience of surgeons in many parts of the world has proved the soundness of this procedure. He now adds a description of his more recently designed V-arthrodesis of the hip. Whether this will become equally popular remains to be seen: an incidence of nearly 10% of fractures of the femur as a complication of its early stages is rather disquieting. In view of the present surge of feeling towards arthroplasty, it is perhaps healthy to be reminded of the advantages of arthrodesis by someone as expert and enthusiastic as Mr. Brittain.

THE LANCET

LONDON: SATURDAY, OCT. 25, 1952

Congenital Tuberculosis

Some medical conditions are truly rare; others, once thought to be rare, prove less uncommon when rigorously sought. This second group would seem to include congenital tuberculosis. In 1935 Beitzke[1] found reports of 61 proved cases of congenital tuberculosis with morbid anatomical lesions, and of a further 40 in which tubercle bacilli were recovered from the fœtus without any apparent histological change. Hughesdon,[2] surveying the period 1935–45, found an additional 11 proved cases and 15 "probables"; and the total of acceptable case-records is now around 130.

The main source of infection is the placenta, bacillary thrombi developing in the intervillous space because, in Loewenstein's[3] words, "circulation in these lagoons is very slow." After direct invasion of the fœtal blood-stream via the umbilical vein a primary complex may be established in the liver and the glands of the porta hepatis or, if the bacilli by-pass the liver via the ductus venosus, in the lungs and hilar glands. The fœtal tissues being in the first instance non-allergic, simultaneous primary infection of liver and lung can also occur; hence the finding of primary complexes in both organs. When a tuberculous placental focus ruptures into the amniotic fluid the fœtus may either swallow tubercle bacilli and develop mesenteric lesions or inhale the bacilli during the course of labour, so that multiple primary foci develop in the lungs and hilar glands[4]; bacilli may also be aspirated into the eustachian tube and middle ear, again causing lesions of primary type. A further possible source of infection, after the membranes have ruptured, is material from a tuberculous endometrium. The various routes and modes of infection can thus give rise to a disease-pattern of considerable complexity, which may be further complicated by direct droplet infection from the mother's breath after birth. The clinical course of the illness is generally disastrous; the infant soon fails to thrive, and generally dies within two months from miliary tuberculosis. One important factor in the accelerated postnatal progress of the disease is the increased level of tissue oxygenation compared with that in the fœtus, which depends entirely on the placental blood-supply for its oxygen. Vorwald[5] demonstrated in the fœtal guineapig high resistance to tuberculous infection even after injection of the bacilli directly into the fœtal tissues in utero. The expansion of the fœtal lungs at birth, before the umbilical cord is tied, may also flood the newly opened pulmonary circulation with tubercle bacilli, leading to miliary foci throughout these organs. After birth, as Rich[6] points out, the abundant oxygen supply to the lungs, combined with the facts that the blood-supply to the liver is largely venous and that much of the available oxygen is consumed by the hepatic cells themselves, may favour the more rapid development of the pulmonary lesions, so that by the time of death these may be much the more prominent.

Placental tuberculous infection does not necessarily result in invasion of the fœtal circulation, nor is such invasion inevitably followed by tuberculous disease; organisms are sometimes recovered from the fœtal heart blood with no evidence whatever of disease in any organ. Indeed, the possibility of occasional recovery from congenital tuberculous disease cannot be discounted; certainly survival up to the age of 26 months has been recorded by Hughesdon; and presumably there can be slight, as well as severe, intra-uterine infections, according to the number of bacilli released. Most earlier accounts have described or assumed the presence of extensive disease in the mother. As Harris and Trenchard[7] indicate, however, there is a strong likelihood that the early hæmatogenous dissemination of organisms after primary infection may result in infection of the placenta. The finding by Choremis and Pantazis[8] of positive bone-marrow cultures in a high proportion of cases with a recent primary complex supports this view. Such a dissemination occurs more freely before allergy develops, and the initial implantation of bacilli in the placenta may even take place within the first few weeks after entry of the organisms into the mother's body. Certainly the plea that women who develop any significant primary or early post-primary tuberculous lesions during pregnancy should be carefully supervised is amply justified, and probably such patients should receive chemotherapy as well.

Congenital tuberculosis is one of the conditions awkwardly placed on the frontiers of various specialties. The chest physician, obstetrician, pædiatrician, and pathologist are all more or less concerned. Combined effort should ensure, however, that no gap exists where the frontiers meet. Measures that might be considered include routine radiographic examination of the chest of all pregnant women; bed rest and chemotherapy for those found to have active lesions (including primary infection with visible pulmonary or glandular foci, erythema nodosum, and particularly pleural effusion); routine pathological examination of the placenta of tuberculous mothers; and culture for tubercle bacilli of the lochia and of blood from the umbilical vein where the mother has, or has recently had, active tuberculous disease. A suspected infant should have a tuberculin-jelly test and perhaps a chest radiograph at weekly intervals, since early chemotherapy might be life-saving.

Dental Treatment of Children

UNDER the Dentists Bill the new General Dental Council would be enabled to follow the New Zealand precedent and allow ancillary workers to perform simple dental operations, under professional supervision, in the public-health services. The British Dental Association has sought to prove that such a step is not only undesirable in the public interest but also unnecessary. The dental profession has always argued that it could treat satisfactorily the "priority classes" of the community, and that the reduced demand for treatment after the imposition of charges under the National Health Service would free enough dentists to restore the school dental service, which has virtually broken down since the health service began in 1948. Many more young dentists, it was contended, would wish to enter the local-authority dental services, since they would find fewer openings as assistants in private practice; while the reduced demand on practitioners would enable them to devote more time to the treatment, in their own surgeries, of school-children and expectant and nursing mothers.

The increase in the number of recruits to the local-authority health services has turned out to be much smaller than was expected by some prophets; for it has made no significant impression on the staffing problem of the school dental service, and there are still very few parts of the country with a full complement of school dentists. The British Dental Association has accordingly sent a questionary to all practising dentists throughout the country asking them whether they are willing to treat children in their practices and, if so, how many hours each week they are prepared to set aside for this purpose. From the replies it appears that private practitioners are between them prepared to devote 10,000 hours a week to treating children; which, according to the association, would suffice for the treatment of a million children per annum. It would be more accurate, however, to say that, working for fifty weeks in the year, these practitioners would set aside annually one million half-hour sessions for the children. Thus each year one million children could each be seen once, for half an hour. But very few children can have all the dental treatment they need in a single half-hour session each year. The average number of visits to the dentist by every child who needs dental care is at least four each year; and little of permanent value can be done if each session is shorter than half an hour. Thus, on the most optimistic estimate, the returns suggest that an additional 250,000–300,000 children could be properly treated. Any scheme based on the willingness of dental practitioners to devote 10,000 hours weekly to their child patients can obviously reach only an insignificant fraction of the 6–7 million school-children in the country, of whom at least 80% require continuous dental care. Far from supporting the case against the legalisation of dental ancillaries for simple routine dentistry, the results of the British Dental Association's initiative seem to show that these ancillaries are essential if dental treatment for the vast majority of our children is to go beyond the emergency extraction of teeth for the relief of toothache.

It is perhaps not surprising that of the 10,000 or more practising dentists in the country, more than four-fifths have indicated their unwillingness to treat school-children. The work is mainly routine and holds little interest for the highly trained dental surgeon. For this reason, the proposal to train ancillaries specifically for simple operations, and to employ them in clinics under professional supervision, must seem to the unprejudiced observer of the neglect of our children's dental health an unexceptionable development. The British Dental Association's investigation demonstrates that without this step the neglect will continue. In the Parliamentary session that is now ending the Bill passed through all stages in the House of Lords[1]; but unfortunately, in the press of business, it did not come before the House of Commons. We hope that in the new session the Government will not forget it.

New Views on Bronchiectasis

THE pathogenesis of bronchiectasis has long been a favourite subject of medical controversy: LAENNEC considered that the bronchi were dilated by their retained secretions; STOKES, of Dublin, taught that the condition arose when the bronchial walls were weakened by inflammation; and others have since attributed the dilatation to fibrosis or to congenital defects in the bronchi. In the last twenty years, largely as a result of the work of LEE LANDER and DAVIDSON,[2] the importance of peripheral collapse of the lung has received a great deal of attention. It is argued that mucus is aspirated into the peripheral bronchi, leading to collapse of the affected area of lung, and that this collapse increases the negative pressure in the pleural space and causes dilatation of the bronchi proximal to the obstruction. This explanation has been widely accepted, but it was challenged by ROBERTS and BLAIR [3] on the grounds of their work on pulmonary collapse in primary tuberculosis; among 77 children with collapse they found 31 in whom there was no suggestion of bronchiectasis and no increase in the pleural negative pressure, though this was not measured in all cases. They considered that in the children who did have bronchiectasis the important factors were retention of secretion and inflammation of the bronchial wall. The wheel has thus come full circle.

The latest contribution to the discussion comes from WHITWELL.[4] He has examined 200 bronchiectatic lungs removed at operation, and he has explored the bronchial tree by serial histological sections, by direct dissection, and by the preparation of neoprene casts. Believing that bronchiectasis is not one disease but several, he has tried to correlate the pathological findings with the clinical picture, and to some extent he has succeeded. He distinguishes three types of bronchiectasis, the atelectatic, the saccular, and the follicular, but even so he was unable to classify a large proportion of his material. The atelectatic type was the least common, accounting for only 10% of his specimens, and it was the only type in which all the bronchi to a lobe were involved; in the other types bronchial involvement was patchy. Here the

whole lobe was collapsed and airless, and the right middle and lower lobes were the ones most commonly affected. This type was usually found in children, but it also occurred in adults. On section, obvious alveolar collapse was seen throughout the affected lobe, and fibrosis and hæmorrhage into the alveoli were common, but, on the other hand, active inflammation was comparatively rare. Whitwell attributes these changes to compression of the lobar bronchus by lymphatic glands which have been enlarged either by tuberculosis or by the adenitis that sometimes develops in measles or whooping-cough. The obstruction was proximal rather than peripheral, and the peculiar vulnerability of the middle-lobe bronchus to this kind of blockage has been stressed by Brock.[5] The term "saccular bronchiectasis" covers the pathological appearances in another and slightly larger group described by Whitwell. Bronchography had usually shown saccular changes, but he is careful to point out that X-ray signs do not correspond closely to pathological findings, and are not a satisfactory basis for classification. On this point he confirms the opinion of Ogilvie,[6] but differs from that of Reid.[7] Saccular bronchiectasis often developed later in life than the other two types, usually after the age of 15, and, in sharp distinction to the atelectatic group, the disease was found in the left lower lobe in three-quarters of the lungs examined. The distribution of the lesions was patchy, segments rather than entire lobes being affected. The saccules showed considerable squamous metaplasia, and chronic inflammatory changes were an outstanding feature, but there was no lymphadenopathy. The saccules did not arise at the periphery of the bronchial tree, but between the first and third branches of the segmental bronchi. They ended blindly and the branches beyond them were obliterated. The pathogenesis of this type is uncertain: there is no direct association with measles or whooping-cough, but about half the cases followed bronchopneumonia; and most of the others began insidiously, though it is impossible to rule out a mild aspiration pneumonitis as the start of the trouble. Whitwell himself suggests that they began as a chronic inflammation in the walls of the medium-sized bronchi.

The third and largest group is the most interesting. This Whitwell calls "follicular bronchiectasis"—a name chosen because the most prominent histological feature is an excess of lymphoid tissue in the follicles and nodes in the walls of the affected bronchi and among the surrounding alveoli. This type follows acute viral infection of the lungs in early childhood, usually after measles, whooping-cough, or bronchopneumonia. Again the disease is spread in patches, and affects mainly the left lower lobe. The dilated bronchi commonly, but not invariably, appear cylindrical on bronchography. In both the follicular and the saccular types, the affected lung is usually well aerated, in spite of the fact (noted by Reid[7] in Australia and Duprez[8] in Belgium) that the affected bronchi end blindly because their distal ends have been destroyed. It has been observed both experimentally and during operations that occlusion of a main lobar bronchus produces collapse of the lobe, which, as the air is absorbed, fills up with its own secretions. On the other hand, when a segmental bronchus is occluded, collapse does not usually follow, though the segment may retain its own secretions just the same, giving the radiological appearances of segmental collapse. If, for any reason, the secretions do not accumulate or are absorbed, the segment will become re-aerated by the collateral circulation of air from neighbouring segments, even though the bronchus is still occluded. This phenomenon was first demonstrated twenty years ago by Van Allen and his colleagues,[9–11] but its importance has only lately been realised, by Churchill[12,13] in America and by Baarsma, Dirken, and Huizinga[14,15] in Holland. Incidentally, this collateral circulation of air provides strong evidence of the existence of Kohn's alveolar pores, which have provoked such controversy in the past. Churchill argues that the collateral air drift cannot serve any respiratory function except that of filling space, because the air that enters the obstructed segment will already be in equilibrium with the blood. A further point to which he draws attention is that the bronchial arterial supply to a segment seems to be increased when the segmental bronchus is occluded. This, he thinks, may establish a pressure gradient great enough to prevent the shunting of pulmonary arterial blood into an area of lung where it would be physiologically useless.

Whitwell's conception of these three types of bronchiectasis as separate clinical and pathological entities of different ætiology may represent a real advance in this difficult subject. Clinically, however, the distinction between his saccular and follicular groups seems to involve little that could not be accounted for by the different age at which the events leading to the bronchiectasis take place. The clinician, who would welcome an explanation which takes greater account of the bronchographic changes, may, for this reason, be attracted by Reid's suggestion that the difference between saccular and other types of bronchiectasis lies in the level at which the dilatation begins and in the degree of peripheral bronchial obliteration.

The Patient's Favour

In his Harveian Oration to the Royal College of Physicians on Oct. 17 Lord Moran recalled that when the college was founded in 1518 its primary purpose was to suppress unlicensed practitioners. It had shown more aptitude for repression than for getting to the root of the trouble—which was that people go to the quack because they think he is better than the doctor. One remedy was to educate the public as to what a good doctor could do, and another was to purge medicine of its elements of humbug. But the real remedy, he thought, was to make it unnecessary to win the patient's favour, and he welcomed the evolutionary process by which, in hospital practice, the fortunes and advancement of the doctor now depend less and less on the patient's likes and dislikes, and more and more on the verdict of his colleagues. The danger in this, Lord Moran said, is that in the cultivation of his science the physician may neglect his art. In the address which we publish on p. 820 Sir Heneage Ogilvie draws attention yet more forcibly to the danger that science may come to be preferred to the patient.

RAPID DIAGNOSIS OF INFLUENZA

THE clinician and the epidemiologist, who have been spoiled by the speed of modern bacteriological diagnosis, are still not reconciled to the unhurried laboratory diagnosis of virus diseases. They should be heartened by a report[1] describing how to determine within three days the type of virus responsible for a case of influenza. Throat washings from the suspected case are inoculated amniotically into fertile hen's eggs from which the amniotic fluids and membranes are harvested two to three days later. These are at once used as antigens in a complement-fixation test to determine the serological type of the influenza virus. Refined techniques can then be applied at leisure if the epidemiologist requires more precise information about the serological subtype.

Much more rapid, although less complete, information is yielded by a test designed by Fazekas de St. Groth[2] and based on experimental studies of influenza in mice.[3] The respiratory mucus of normal mice contains an inhibitor of influenza-virus agglutination which disappears during influenza infection, probably as a result of enzymic action of the virus. Human nasal secretions also contain an inhibitor of influenza-virus agglutination, but its concentration varies greatly between normal people. Fazekas[2] found, however, that the inhibitory titres of nasal secretions for three different strains of influenza virus showed a characteristic pattern which was significantly altered by influenza infection. It is claimed that the test will give an answer within an hour, although it tells only whether infection with influenza virus is present. This test deserves further study; it may be most useful in selecting specimens likely to give positive isolations of influenza virus. Also, under certain circumstances it might help public-health authorities who wished to decide rapidly whether a suspected case was of influenza.

One reason for the long delays in the diagnosis of virus diseases is that the virologist, unlike the bacteriologist, has no single broth on which all but the most fastidious of organisms will feed contentedly. Instead, the laboratory which sets out to isolate different viruses must house many types of laboratory animals in addition to fertile hen's eggs and the paraphernalia of tissue culture. Recently, however, tissue-culture techniques have been applied very successfully to the cultivation[4] and serological identification[5] of the poliomyelitis viruses, which were originally thought to be much more specific in their dietetic requirements than they now appear to be. It may not be too much to hope that further research will one day provide a general tissue-culture technique for growing many different types of viruses which could later be identified by simple serological tests. We might then look forward to the time when cultures will be reported after a couple of days "bacteriologically and virologically sterile."

PARTIES TO ADOPTION

ONLY twenty-five years have elapsed since the first *legal* adoption took place in England and Wales. The first Adoption Act was passed in 1926, and the first adoption orders—2967 of them—were made the following year. Northern Ireland followed suit with an Adoption Act in 1929, and Scotland did the same in 1930; but the Republic of Eire has not yet legalised adoption—a fact which causes social workers here some difficulties. In England and Wales in 1949 the number of adoption orders was 17,331.

There are four ways nowadays in which a child can be [illegible]ered adoption society, through [illegible] of a local authority, through a third person, or directly by the mother or father. Doctors are often concerned in the third of these, as are also nurses and almoners. Margaret Kornitzer, the author of a new book on adoption,[1] regards both the third and fourth methods as very undesirable; and as she is clearly an observer of experience and wide knowledge, and shows herself in most matters tolerant and unprejudiced, her views must command respect, even though she herself is closely associated with registered adoption societies. She regards as the essence of successful adoption the unhurried placing of a child, whose background is fully known, with adopters whose temperaments, motives, and material surroundings have been carefully studied—the careful matching, in other words, of child to adoptive parents, with the interests of the child always pre-eminent. This careful study, she thinks, requires experience and objectivity; and she has found doctors, who are usually deeply concerned with the interests either of the natural mother or of the adopters, insufficiently aware of the dangers to the child of an unsuitable adoption as well as of the infinite unhappiness it may bring to all concerned.

"A gynæcologist dealing with a distraught or bereaved woman patient," she says, "must often be sorely tempted to get her a baby somehow, without thinking what it means to the child. It is unfortunately not unknown for doctors to scour the maternity wards and the nursing homes, and if the search is unsuccessful, importune the local authorities and adoption societies on behalf of an unhappy creature who, 'if she doesn't get a baby soon will be in a mental home.'"

"*It is only fair to say that many doctors are fully aware of the dangers of promiscuous adoption placements and never prescribe as medicine another woman's child.*"

"But there does seem to be a case for educating the medical world in some of the factors that go to making adoption placement a success or a failure and for inculcating a greater sense of responsibility towards the child."

These views deserve serious thought. We have heard of a woman doctor complaining about an adoption society which had refused to provide a baby for a woman with recurrent depressive episodes, just out of a mental hospital. The doctor had taken steps to find a child herself, and was well satisfied with her success. Yet if this therapeutic adoption failed, the child would be irrevocably linked to a melancholic.

Nevertheless Miss Kornitzer's picture is incomplete. Many doctors believe that adoption by affectionate people, even if they are imperfect, exposes a child to fewer risks than does life in an institution. All recent studies suggest that the child's primary need is for direct personal love—which, indeed, appears to inoculate him against many emotional disasters. Better, these doctors would argue, that he should feel much, even painfully, in a place where love is, than starve emotionally in impersonal surroundings. Is it not possible that here we are dealing with a case where the best is the enemy of the good? They might point out, too, that the adoption societies are in the enviable position of having to look after the interests of only one party to the transaction: their concern is solely for the needs of the child. But does that mean that the needs of prospective parents should count for nothing at all? The doctor is obliged to take the welfare of all parties into consideration. His opinion that an emotionally disturbed woman may be helped, sometimes even to lasting recovery, by having a child to look after, is not always, or necessarily, ill founded. The adoption societies say that they have so many applicants and—relatively—so few babies, that it is their duty to select the parents carefully. But this means that parents who do not care to submit to inquiry look elsewhere for a baby—and generally find one. Until e have emptied our institutions and orphanages, we annot pretend that adopters outnumber children; and may be that by insisting on a high standard for the ew the adoption societies are standing in the way of an verage home life for the many.

Their principles, however, should certainly carry great eight with all doctors given to arranging adoptions. childless couple, a lonely spinster, a mother bereaved f a child may all be legitimate objects of sympathy; ut they are full grown, and unlikely to change much. he child is growing and vulnerable: he needs to be iven a fair chance. The doctor about to arrange an doption might pause to consider whether he would hink the home appropriate if the child were his own.

ACTION OF INSULIN ON THE LIVER

THE apparently differing effect of insulin on the liver f normal and of diabetic animals has long been a uzzle. In diabetic animals formation of liver glycogen eems to be increased by insulin, whereas in normal nimals it seems to be decreased. Macleod[1] drew ttention to this anomaly in 1934. Soskin[2] suggested hat any insulin administered to the normal animal was an excess over the optimal amount already present and caused hypoglycæmia; this in turn brought into operation a compensatory hepatic glycogenolysis. The adrenaline mechanism very probably mediates this glycogenolysis in the liver, since removal or denervation of the adrenal glands prevents depletion of liver glycogen following hypoglycæmia.[3] [4] In some experiments with perfused livers,[5–7] however, where hepatic glycogenolysis followed the administration of insulin, adrenaline played no part. In these experiments only certain samples of insulin showed glycogenolytic effects, although all were therapeutically active. Bridge[8] even demonstrated depletion of hepatic glycogen after injecting insulin into normal animals which were protected from hypoglycæmia by glucose infusions or which had been previously adrenalectomised; but he used a brand of insulin later shown by de Duve et al.[9] to contain the glycogenolytic factor, glucagon. Bouckaert and de Duve[10] reinterpreted Bridge's results in the light of this knowledge and concluded that with glucagon-free preparations of insulin Bridge would have observed an increase in hepatic glycogen proportionate to the dose of insulin, provided that the blood-sugar had been kept fairly normal by regulating the glucose infusion. Work by the Louvain school[10] has confirmed the relative preponderance of the hepatic action of insulin over its peripheral action—a theme previously developed by Soskin.[2] With small doses of insulin the ratio of hepatic action to peripheral action is up to 2 to 1, but with very heavy doses it reaches 8 to 1 in favour of the liver. This predominant localisation of the action of insulin in the liver is further illustrated by recent isotope studies on lipogenesis in the liver of the rat. Chernick and Chaikoff,[11] using glucose labelled with C^{14}, have shown that insulin stimulates the incorporation of glucose into glycogen, carbon dioxide, and fatty acids, the stimulation of lipogenesis exceeding that of carbon dioxide formation. It is thus possible that glycogenolysis in the normal liver after the administration of insulin does not necessarily represent increased glucose production, but may be due, at least partly, to increased formation of fatty acids.

Sherlock and her collaborators,[12] who have studied "normal" and diabetic patients by hepatic-vein catheterisation, conclude that the liver is largely, but not wholly, responsible for the fall in the blood-sugar level after an injection of insulin. In normal persons there was a correlation between the diminished hepatic output and increased peripheral utilisation of glucose; but this was not apparent in diabetics, in whom two types of response could be distinguished. In one group, corresponding to the elderly obese diabetic often with cardiovascular complications, the effect of insulin was mainly an increase in peripheral utilisation of glucose but with a relatively slight fall in blood-sugar; whereas the other group—the young thin diabetic with minimal complications—responded to insulin by a large drop in the capillary glucose level, mainly due to diminished hepatic production. Aspiration biopsy of the liver showed normal liver cells in the hepatic-sensitive group and fatty change in the hepatic-insensitive group.[13]

It now seems possible to have a unitary conception of the action of insulin in normals and diabetics; for insulin has been shown consistently to stimulate formation of liver glycogen, if freed from the opposing effects of hypoglycæmia with release of adrenaline and of contaminating glucagon derived from the pancreatic α cells.

HEALTHY DOCTORS

SHOEMAKERS' children are said to be ill shod; and, if the truth were known, their fathers' boots are probably often in a worse condition than theirs. Undaunted by this legend of occupational hazard, however, Dr. Cuthbert Dukes, in his search for the causes of good health, boldly addressed an informal questionary to some of his colleagues. His confidence was justified, and in his presidential address to the Medical Society of London on Oct. 13 he was able to describe the reasons given him by 50 doctors, including 23 fellows of the society, for their own good health. As his controls he chose 50 non-medical men of the same age-group and social grade. He had intended to include 50 women to complete his series of controls, but he gave up this project when still 10 short of the mark, because he found that women attributed their good health to such irrelevant and non-masculine reasons as having a baby, the use of the paint-box, or an unsympathetic husband.

Having accordingly abandoned the female sex, Dr. Dukes restricted his analysis to the straightforward replies of the men. Most of them attributed their good health to five reasons: open-air physical exercise, such as walking, gardening, or golf; congenial occupation (this was mentioned by several doctors and seldom by the lay controls); some precaution adopted after a former illness; temperate habits in smoking, drinking, and eating; and successful emotional adaptation to the strain of life, which they usually described by some such phrase as "learning to take life the right way." Dr. Dukes did not claim that these answers were new or unexpected, but his researches did suggest that an inquiry into the private precautions which people adopt to keep fit might yield interesting results.

In the *Shorter Oxford Dictionary* health is defined as "soundness of body, that condition in which its functions are duly discharged." But Dr. Dukes would like to extend this definition to read "discharged harmoniously"; for harmony in his view is an essential characteristic of health especially when we think "in terms of body, mind, and spirit." Indeed he wondered whether perhaps we gave ourselves enough credit for our own good health. We were apt to forget the struggle some of us had had to make the "stubborn body become a willing servant to the spirit." But those who had learnt the lesson "enshrined in ancient wisdom and confirmed by modern

science that body and spirit are not two but one," had, he believed, achieved true health. He was the more surprised that only one of the doctors answering his questionary had spontaneously spoken of the importance of religion in relation to health. But Dr. Dukes is convinced "that the little working bit of a man's religious faith, not his outward professions or his theological creed but his inward secret convictions—these must ultimately influence his health to some extent, and might, if given more scope for expression, often improve it."

OXYGEN THERAPY

THE use of high concentrations of oxygen is now well established in the treatment of many conditions; and owing to advances in technique a continuous supply of this gas at concentrations of 60% or more can be assured. This improved efficiency in administration should give rise to further thought on the indications and dangers of the agent. Hitherto there has sometimes been a tendency to regard oxygen as a harmless physiological substance which "if it does no good, at least will do no harm." It is increasingly clear, however, that oxygen therapy must be applied with circumspection.

In chronic pulmonary disease, and notably emphysema, there is commonly a considerable accumulation of carbon dioxide in the arterial blood. If oxygen is then given the pulmonary ventilation diminishes owing to the cessation of anoxic impulses from the carotid body; further retention of carbon dioxide results from the hypoventilation, and toxic levels may be reached. This train of events has been noted in the course of normal oxygen therapy.[1] Bouterline-Young and Whittenberger[2] suggest that where anoxæmia is accompanied by hypercapnia effective pulmonary ventilation must be maintained by artificial respiration while oxygen is being administered.

Storstein[3] submitted three groups of patients to cardiac catheterisation and measured their respiratory and circulatory responses to the inhalation of 97% oxygen for one hour. His first group comprised healthy people rendered acutely anoxic by the inhalation of low-oxygen mixtures. His second group was composed of patients with chronic pulmonary disease; this group was divided into those with evidence of cardiac failure (cor pulmonale) and those without past or present signs of heart-disease. The last group consisted of patients with various chronic heart lesions. The respiratory responses tended to confirm the observations of other workers; and as the experimental conditions were not ideal for respiratory stability Storstein concentrated on the circulatory findings. By measuring the pulmonary arterial pressure he found that pure-oxygen breathing reversed the pulmonary hypertension induced in healthy people by administering low-oxygen mixtures. Where, however, anoxia had long been present, as in his chronic lung-disease group, the lowering of pulmonary arterial pressure was far less striking. He suggests that with chronic anoxia early and efficient oxygen therapy might prevent the pulmonary vascular changes from becoming irreversible. Calculation of the cardiac output and work of the right ventricle in his three groups showed that not only was the work of the right ventricle greatest in the cor-pulmonale group but that it was actually increased by the administration of 97% oxygen. This undesirable effect was due to an increase in cardiac output without compensatory reduction in pulmonary arterial pressure. Chronic anoxæmia is a persistent stimulus to high cardiac output even in the presence of cardiac failure; and when irreversible pulmonary hypertension is present long-continued administration of oxygen will place an increased strain on the already over-burdened right ventricle.

The administration of oxygen in high concentrations to the premature newborn infant has become a routine in many nurseries. That this measure may not be wholly beneficial has been demonstrated by Jefferson,[4] who has shown that the incidence of retrolental fibroplasia in premature infants is closely related to the fashion of oxygen therapy. Incidence was greatest among infants who had been suddenly removed from an atmosphere containing 60% oxygen to room air. When removal from the oxygen atmosphere was made more gradual, the incidence of retrolental fibroplasia was lower. Equally striking is her success in treating babies with early signs of the disease by replacing them in high concentrations of oxygen for a long time before gradually reducing the concentration.

INCIDENCE AND PREVALENCE

WHEN medical statistics were concerned mainly with mortality, problems of terminology were few. Death is an unequivocal fact, and it comes only once to each person. The epidemiology of acute diseases is also fairly straightforward, in that the affected can usually be clearly distinguished from the unaffected, and the outcome—recovery or death—is apparent within days or weeks. But the epidemiology of more chronic disorders may be complicated by a gradual onset, so that a person who regards himself as in normal health may be shown to be in the early stages of serious disease. Furthermore, the patient may remain affected for a long time; and this complicates surveys and the terminology in which their results are expressed.[5]

One of the chief trouble-makers is "incidence." Some years ago Hogben[6] objected to the practice among medical writers of using this word when "frequency" was meant. A record of the number of cases in age and sex groups is a "frequency" distribution. To justify the use of "incidence" it is essential to know the size of the population from which the cases are drawn, so that the result may be expressed "per 1000" or "per cent." But even then "incidence" may be used in any one of three different senses: (*a*) for the number of cases per 1000 examined at a given time; (*b*) for the number of cases per 1000 examined, developing during an unspecified time in those known to have been normal originally; (*c*) for the number of cases developing during a known period in those known to have been normal at the beginning of the observation period, expressed as, for example, "per 1000 per annum."

The third of these is more usually known as an "attack-rate." To the first—namely, the number of cases per 1000 examined at a given time—American workers apply the term "prevalence"; and this has much to commend it. To most people "incidence" conveys the idea of the onset of some new condition; but a mass-radiography survey, for example, includes cases that have existed unknown for many years, and the term "prevalence" seems etymologically more justifiable than "incidence." Stocks[5] recognises this, and defines "monthly prevalence-rate" as the "number of illnesses present in the population at any time during the month, regardless of when they began, per stated number of population." If "prevalence" were to be generally adopted for the results of surveys applied once only to populations of known size in which the time of onset cannot be known, and "attack-rate" were used when both the population and the duration of risk are known, then "incidence" with its ambiguities could largely lapse, or be restricted to the second meaning—i.e., new occurrences in a known population during an unspecified time.

one method of treatment, the more is his general education wasted, the more he approximates to a technician—in fact, the more easily he can be replaced by a technician. Many of the laboratory tests that were introduced by doctors and that were formerly performed by doctors, are now handed over to technicians. Blood-counts, sedimentation tests, estimation of blood-groups, urine analyses, blood-pressure readings, the taking of electrocardiograms and of X-ray films, these are now done for the most part by technicians. A doctor is in charge and does the final interpretation, but the technicians are constantly improving their education and taking an increasing interest in the uses to which their work is put; they often make their own interpretation, they often think their opinion is as good as the doctor's, they are often right.

In many foreign clinics all the anæsthetics, even those for severe and long operations, are given by technicians; a qualified anæsthetist sits in a central office nominally in charge, and ready to appear in any theatre if the technician presses an alarm signal, but he is seldom needed. In New Zealand much of the work of dentists has been handed over to nurses, and in Britain a Bill has been introduced allowing such a scheme to be tried here. It is easy to see how a ruthless Minister of Health, determined to reduce the cost of the service and to break the cartel of doctors, could set about to dilute labour. An optician would see all cases referred to ophthalmic outpatients, keeping only the unusual ones for the ophthalmologist. A nurse, given a course in the use of specula, could, with the help of a welfare worker, deal with two-thirds of the otolaryngological outpatients. A chiropodist with a box of Scholl's supports would lighten the work of the orthopædic surgeon at outpatients, and a plaster technician would do the same for him in the theatre. In general surgery the meticulous but tedious work of opening and closing wounds could be handed over to an unqualified assistant, allowing the surgeon to do twice as many operations in a session. Fantasies can come true. The Erewhon of today may become the Erehwemos of tomorrow.

HEALING OR SCIENCE?

Had we asked ourselves twenty years ago "What is the purpose of medicine?" we should have answered "to heal the sick." The patient then regarded his own doctor as one to whom he could bring all his troubles and from whom he could seek advice in all his difficulties. He respected the consultant, and he was willing to attend hospital to undergo tests and be informed of the result. But only if the verdict was confirmed by his own doctor, the man who knew his virtues, his failings, and his idiosyncrasies, and who understood him as an individual, was he willing to accept the advice and to act upon it.

How have we departed from this relationship? Possibly in two ways, in the ideal for which we are working and in the place we hold in our patients' regard. Were we to ask modern students "What is the purpose of medicine?" none would answer "to heal the sick"; that is too Biblical, too Victorian, too sentimental. They would say "to prevent illness" or "to discover the cause of disease," a scientific rather than a humanitarian ideal. In becoming scientists rather than healers, in making the centre of our interest the laboratory rather than the bedside, in organising ourselves and our work on a nation-wide basis, we are losing that personal contact which has characterised medicine since prehistoric times. In handing over each aspect of disease to a specialist, we have removed the doctor from his age-old rôle of friend and adviser. The patient, taught by the journalist in search of copy and the manufacturers looking for increased sales to demand the newest form of treatment, is prone to look on the general practitioner merely as a supplier of the commodities he desires, and a fixer of appointments with the specialist of his own choice. Whereas formerly he came to his general practitioner saying "I am sick, I want your help," he now says "I have a pain, I want an X ray; I have fever, I want 'Chloromycetin'; I have rheumatism, I want cortisone."

Dr. F. M. R. Walshe, speaking seven years ago on the Integration of Medicine, drew the distinction between physiology, which he described as a liberal profession because it pursues knowledge for its own sake alone, and medicine which is a useful profession because its activities are directed to an end, the health and well-being of the community. Our present tendency is to transform medicine from a useful to a liberal profession, from an applied to a pure science; to seek knowledge for its own sake rather than to attempt the application of knowledge already acquired for the good of the patient; to look on sickness as an intellectual rather than a human problem. In this trend we find another influence undermining the relation of mutual trust that has always existed between the doctor and his patient. If the patient is coming to look on the doctor as a man in a white coat behind the counter of Welfare Incorporated, Universal Providers, picking the right remedy out of the right drawer, wrapping it up and handing it over, the doctor is coming to look on his patients as customers, on disease as an intellectual problem for solution, and on the sick man as experimental material to be studied in the search for knowledge rather than as a fellow human being in need of help.

The science of experimental medicine is something new, and, to those brought up in the Hippocratic tradition, something sinister; for it is capable of destroying in our minds the old faith that we are the servants of the patients whom we have undertaken to care for, and in the minds of the patients the complete trust that they can place their lives, or those of their loved ones, in our care, knowing that we will help them *if it is in our power to do so. To the exponent of experimental* medicine the patient may no longer be the most important person in the room. In the search for knowledge, we may lose something far more precious.

Experiment is not new. Harvey, Hunter, Jenner, and Lister were all experimenters. The man who in his work comes across a question new to medicine to which he must find an answer, can do so only by experiment. What is new is the cult of the experimental method for its own sake, not to find the answer to a specific question but in the hope that by experimenting with sufficient persistence some questions will be stirred up, not as an intellectual discipline for those who are likely to become *investigators*, but as a routine exercise for all students. What is new is research by fraud, the performance on patients who have come to us in good faith for the cure of their ailment of any number of tests and investigations, many of them unpleasant, some of them dangerous, all of them unnecessary for the diagnosis or treatment of their ailment, but performed in a general search for information, or merely as a bit of practice in technique.

THE PLACE OF RESEARCH

The discovery of the cause of disease and the prevention of disease are admirable aims that we must pursue as vigorously as we can; but the treatment of disease is the immediate problem for which we have been trained and which we must tackle, and it will not wait. If practical medicine and scientific medicine are indeed in competition for money, material, and man-power, practical medicine must have first claim on available funds and prior place in the training of the medical student, and research must do the best it can with what can be spared for it. The efficacy of treatment is largely dependent on the money spent upon it: the efficacy of research is not, for the most important discoveries have usually been made by humble men working in garrets with home-made apparatus. Further, treatment is local and personal, benefiting those whose labour pays for it. Research is global, impersonal, and available to all the world alike. Penicillin is distributed among the nations, not in proportion to their contribution to its discovery, but in proportion to their ability to buy the finished product. Pure science is a luxury, and, like all luxuries, must be paid for by production of commodities.

How then should we divide our resources between research and treatment, in order to get the best from each? Is not the first necessity to employ scientists to investigate and clinicians to treat, and to abolish the clinico-scientific Pooh-Bah? We find it a little difficult to assess research at its true worth, because of the box-office glamour with which it is at present associated. The novelist or the film-script writer cannot hope to make a doctor the hero unless he is employed in research. The dying financier makes his peace with both worlds by leaving his money to research. The dean of a university can be hard-hearted to any appeal for further expenditure unless it is intended for research. The man in a white coat who talks a jargon unintelligible to his fellows is looked on as a superior being. But what is research? Constant inquiry, the striving to shine the light a little further into the darkness, the quest for truth; a little touch of genius and a lot of hard work. But the genius and the hard work are very seldom contributed by the same man. Originality cannot be discovered by appointment committees or attracted by grants; it will reveal itself in spite of discouragements and make opportunities where none are offered it. And genius and originality are a very small part of research, merely the spark that sets the machine in motion. The greater part of research work is done by dull, unambitious yes-men, who do not need the training of the clinician because their work is limited to a narrow field, who do not need the brains of the clinician because they follow a programme planned for them from step to step and repeat the same observation day after day, who do not need the courage of the clinician for they lock up the laboratory at five every evening and draw their pay, results or no results.

We must treat research as something vital and not, as we tend to do today, as a parlour trick. Even though the scientific discoveries of the whole world are as open to us as ours are to them, we must still conduct research within the limits of our budget, even if it have no higher purpose than an intellectual stimulus, a flag that must be kept flying. But how shall medical research be organised?

I recently spent a week with a member of the senate of a young and progressive university with a medical school. He had to deal with a number of enthusiasts, each of whom wanted a research department, and on the surgical side alone there were at least six groups who had plans ready for approval—the general surgeon (who had an ambitious programme for the study of gastric function), the vascular surgeon, the ophthalmologist, the otorhinologist (who proposed a joint project with the endocrinologist), the orthopædic surgeon, and the urologist. Each had a group of problems to be solved, each had a team of juniors eager to solve them. Should each department be given its own research unit? if so, how much space would each need in the enormous laboratory building that would arise; how could duplication of apparatus and technicians be avoided; and what would happen when the problems of any particular group were solved and no fresh ones were propounded, when the enthusiastic junior who had been the driving force of the investigation left to take a chair elsewhere?

I ventured to bring forward the view I have held for many years, that research is too important to be entrusted to a doubly unqualified amateur with a foot in both camps. Research demands a long and arduous training
that is almost wholly divorced from that of the bed
a devotion that is lifelong. I suggested that in e
medical faculty there should be at any rate four c
equal in status and salary—of medicine, surgery, g
cology, and clinical research. The research prof
would be a scientist with a medical degree rather th
doctor with scientific leanings, and his department w
be closely linked with the others. He would attend
rounds and give regular lectures in the clinical co
Every registrar would serve at least a year under
to gain an insight into the scientific method. The p
lems that arise every day in the wards would be t
straight to him and not shrugged aside as they are
and he would give perhaps a straight answer, sugg
few experiments that could be carried out in the w
or plan a research project that would be carried ou
his department and under his supervision by mem
of the department concerned.

LIBERTY AND OPPORTUNITY

Chief among our aims in medicine should be
restoration of that liberty of action and equalit
opportunity which is every man's birthright, and w
alone can ensure that the profession makes its
contribution to the welfare of the State. No lo
must the first step in medical practice be final
irrevocable, but each man should have the opportu
to develop his work in the direction that his ambi
leads him and to rise to a position that his ability just
The best should be able to get to the top by merit,
not so good should not drift to the top by seniority al
The general practitioner should be relieved of such o
work as is not medical, and for his medical work
should be rewarded for its quality rather than by
number of patients on his list. He should have ac
to hospitals, to libraries, and to laboratories, and
allowed to keep in touch with his patients in t
serious as well as their minor ailments. He should
able to study intensively aspects of medicine in w
he is interested and for which he shows an aptitude,
eventually to take higher degrees; but he should
be eligible for merit awards on the quality of his gen
practice alone.

The specialist, no less than the general practitio
should have the opportunity to develop according to
talents and to grade himself according to his ability
move sideways as well as up or down. The pre
division of specialist practice into two levels, regis
and consultant, takes no notice of the constant prog
in experience and skill that every man should make
of the great differences in the rate of that progress
are apparent to his fellows. A division that correspo
more nearly to reality, in surgery at any rate, is that of
Services into five grades—trainee, graded surgeon, surg
specialist, officer in charge of a division, and consult
All these are honourable ranks that would be accep
in civil life without the resentment engendered by te
such as "senior hospital medical officer," and al
them correspond to a definite step on the ladder
maturity.

GETTING AND GIVING

We have in our life-time been privileged to take
in the greatest advance in the history of the healing
an advance so great that we are in danger of losing
sense of direction in the exhilaration of the forward r
A forward rush is an advance only when it is consolida
a discovery is an advance only when it is integrated in
body of knowledge, an airborne landing is an adva
only when the parachutists have made contact with
troops on either side and re-established their line
supply. The advances in which we have all participa
and in which we may be engrossed to the exclusion of
else, will help the whole course of medicine only if
keep touch with the great profession in which we

enrolled, remembering that its main purpose is to heal the sick, to preach good tidings to the meek, to bind up the broken-hearted, to give unto them beauty for ashes, the oil of joy for mourning, the garment of praise for the spirit of heaviness.

If we are to integrate our own discoveries and our own skill into this idea, we must never lose sight of the fact that the science of medicine is the instrument whereby the art of medicine is made effective, that the keynote of that art is the spirit of service, and that in our common enterprise the importance of each subdivision must be measured by what it can give, not by what it can get.

Medicine and the Law

"Should a Doctor Tell?"

WHERE it is a question of a member of the medical profession giving evidence in court of matters which have become known to him in the course of treating a patient, the profession claims to observe a standard higher than that of the law. Perhaps these cases would be more frequent were it not that judges are sufficiently sympathetic not to insist upon disclosure. The public does not always appreciate that the doctor who claims privilege does so in the interests of the patient and not in those of the profession. It follows that the patient can, if he wishes, release the doctor from the obligation of secrecy.

In a recent case at Wolverhampton,[1] where a man was charged with having attempted suicide, a hospital doctor quite rightly expressed his reluctance to give evidence against his patient. The police superintendent who was prosecuting, unaware perhaps of the implications of the Hippocratic oath, complained that the doctor had not given the police a statement on the condition of the accused; "this is the first time in my 25 years' police experience where we have failed to get a statement from a doctor at the Royal Hospital; it is most important that we should get it." Well, the importance of a piece of evidence to the prosecution is not the final test of its admissibility. The clerk to the magistrates intervened to comment that in many other courts doctors give evidence almost daily; "do you," he asked, "intend to give this evidence or not?" When the doctor replied "if you direct it," the chairman observed somewhat less insistently: "we do not direct it; we request it." To which the doctor rejoined: "if the patient gives his permission." The accused, who pleaded guilty, assented; the witness thereupon stated that, when he examined the patient on his admission to hospital, he found his condition to be consistent with his having taken an overdose of phenobarbitone. Thus honour was satisfied on all sides.

There is no need now to repeat that the only form of absolute professional privilege recognised by the law is the obligation of secrecy between members of the legal profession and their clients. A learned judge long ago expressed the view that to peer into the private communications passing between barristers or solicitors and their clients would be to purchase the truth at too high a price. For only one profession, however, is the bargain deemed unconscionable. There is no principle, said Lord Jessel in Wheeler *v.* le Marchant (1881), that every confidential communication necessarily made for the purpose of carrying on the ordinary business of life is protected. "The communications made to a medical man whose advice is sought by a patient with respect to the probable origin of the disease as to which he is consulted, and which must necessarily be made in order to enable the medical man to advise or to prescribe for the patient, are not protected. Communications made to a priest in the confessional on matters perhaps considered by the penitent to be more important even than his life or his fortune are not protected." It is nevertheless on record that in Broad *v.* Pitt (1828) Chief Justice Best had declared that he, for one, would never compel a clergyman to disclose communications made to him by a prisoner, although, if the clergyman chose to disclose them, he would receive them in evidence. The textbooks show, too, that Baron Alderson observed in R. *v.* Griffin (1853) that communications made by an accused person to a priest ought not to be divulged. Evidently there are learned judges who, no matter how grave the dilemma of the prosecution, shrink from exposing a witness to this severe ordeal.

The doctor in the witness-box can at least hope to be lucky in his tribunal. On the other hand, if courts are directly faced with the issue they are obliged to enforce the rigour of the law. In the divorce case of Garner *v.* Garner (1920) it was ruled that a doctor might be compelled to give evidence that his patient was suffering from venereal disease, even though the patient was being treated under a scheme governed by statutory regulations which enjoined absolute secrecy upon the doctor—a decision exhibiting a conflict of principle which should never have been allowed to arise.

Public Health

Notification of Infectious Disease

DR. G. A. W. NEILL, medical officer of health for Barnsley, in his report for 1951 describes defects in the notification of infectious diseases.

"In the latter part of the year," he says, "a number of incidents occurred which indicated that there is considerable laxity amongst general practitioners regarding the notification of infectious diseases. Cases have occurred where practitioners have notified persons as suffering from infectious disease without actually having examined them. Practitioners have failed to notify cases under their care or have even notified persons who do not exist at all as suffering from an infectious disease. There are also some practitioners whose patients must be immune from infectious disease as no notifications are ever received from them. But perhaps the most serious default in relation to notification is the delay that has occurred in some cases. This delay is particularly dangerous when it occurs in cases of food poisoning. Members of the medical profession do not seem to be aware that there is an absolute statutory duty imposed upon them by the Public Health Act, 1936, S.144, under pain of a penalty of 40*s.* in default, to notify infectious diseases to the Medical Officer of Health *forthwith.* It is not, of course, the desire of the Health and Sanitary Authority or its officials to add to the proper work of the already over-burdened practitioner. At the same time the Authority has a duty to discharge its statutory obligations and to exercise its powers to preserve the health of the community."

Dr. Neill goes on to suggest that the law relating to notification might with advantage be critically reviewed. "For example, it might be considered advisable to delete some of the diseases which are now notifiable and to add others which at present are not. Furthermore, there is the question of the notification fee which has remained at 2*s.* 6*d.* per case since the Act became law in 1936."

Eire in the Second Quarter

In Eire during the June quarter of this year[1] the birth-rate was 23·8 per 1000 population; this was 1·3 above the rate for the second quarter of 1951. The death-rate was 11·8 per 1000 population (1·8 below that for the second quarter of 1951). The death-rate from tuberculosis was 0·6 per 1000 population (respiratory 0·5, other forms 0·1), compared with 0·8 (0·6 and 0·2) in the second quarter of 1951. The maternal mortality rate was 1·3 per 1000 births registered, compared with 1·7 for the second quarter last year; and the infant-mortality rate was 35 per 1000, compared with 46 for the second quarter last year.

In England Now

A Running Commentary by Peripatetic Correspondents

NOTHING reminds me so strongly that I belong to the fringe of a noble profession as the news, when I telephone at 10 A.M., that Doctor X is in his bath because he has dealt with three confinements (or two road accidents, or a maniac) since midnight. In a lifetime spent in consulting omphaloscopy, the number of times upon which professional duties have called me from my bed between shuteye and the seven o'clock cup of tea is statistically insignificant. When, and if, I rise earlier it is—I was going to say for pleasure, but that is a lie—it is for recreation. I wish that I could boast that it is the ascetic joys of wild-fowling that drag me from my warm and downy in the dead hours: I do not carry the pursuit of pleasure to such extremes. But to join my friends in hounding a few fox cubs to a premature end on a dewy morning in the apple season is—against my moral judgment—a delightful self-indulgence. Never does Nimrod's third-best coat look so fine a scarlet as in the early sun; never does his horn send such sensuous frissons down my spine as in the quiet air of dawn; never are neighbours so neighbourly and foes so far away. But, as the alarm-clock goes off deep in the silent pool of night, my only instinct is to write a cheque, a large one, for the League against Cruel Sports, and then to turn over quickly. I resist and, having stifled the din, in quick review I see the unanswered letters, the unpaid bills, the unspoken retort—and I feel sick. Shaving, that primæval curse, makes me feel worse, nor will cocoa from the 'Thermos' or porridge from the hob remove the nausea, though they help to banish recollections of my sins of omission. But—and this is my discovery—one tablet of amphetamine (or any of the related drugs which come by sample post) banishes my nausea in a trice (whatever that may be) and I can face the morning with bloodthirsty cheerfulness. I recommend it to all who rise early from necessity or choice.

* * *

On Sunday, feeling that "Prolongation of Action of Hypotensive Drugs" "and Venous Velocity in Bedridden Patients" were not exactly my choice of reading for a wet afternoon, I turned to the last column of the last page of *The Lancet*. There, under the heading "Miscellaneous," I found more than enough to keep me happy. For instance, the Cameroons Corporation want an M.O. There are opportunities for surgery and free light and fuel. That sounds better than England, though a children's allowance to a maximum of two seems a bit hard. However, in the next paragraph an R.M.O. is required for a Tin Mine and the basic salary is £1800. This is certainly better than our basic £300. The third paragraph, which offers a beautifully furnished maisonette in Harley Street, with someone to answer the phone and open the door, sounds even more in my line. If I take the flat I'll certainly buy the Cambridge Electrocardiograph in perfect condition in its leather case. While sitting in my Harley Street drawing-room I will surely have time to read the *Works of Ambrose Parey* published in 1649 and may even study the genuine 17th-century maps. Now I'm getting into the spirit of the thing I decide without hesitation to send my Rolls and Bentley to be serviced at Croydon 7464. With so many good things in prospect it's about time I started to count my blessings; and to what better place could I go to do this than to Friends Meeting House, which in the next paragraph offers information on Quakerism? I'm nearing the bottom of the page, and my spell of daydreaming is almost over, but there are still two paragraphs left. So I'll get my old testimonials copied and duplicated by Victoria 0141. It will cheer me up to read ten times over that twenty years ago I was a keen and conscientious house-surgeon and that it gave an eminent gynæcologist great pleasure to announce this fact. Alas, time does not stand still, and today I have difficulty in diagnosing a fœtus and a fibroid. But "Miscellaneous," helpful to the last, offers to do it for me in 24 hours.

* * *

Clever chaps, some of my fellow correspondents; but I'm not sure that they're wise in boosting all this statistical stuff. I know it's right up to date and that degrees of freedom and randomised replicates are jolly good things to have knocking about an article. A sprinkling of Greek letters, too, does make a thesis look pretty hot, if you see what I mean. But it isn't always quite so easy to handle them as people make out. Put in a χ^2 where there ought to be a σ and some examiners get quite mad. Can't see that it matters myself, but there it is; can be dangerous. There is a good deal to be said for having a piece of straightforward clear English—like the Great Masters of Medicine have always used. You can't go wrong on that and it goes down well with the simple chaps—chaps in the clinical units and the editors of the weekly journals. Anyway that's how I am going to write up my Observations on Three Cases of Generalised Osteitis Fibrosa Cystica.

The first case was quite clear. On account of its social class (member of the Athenæum), occupation (bishop, rtd.), age (approx. 92), and so on, there was no doubt that the accepted treatment of choice was contra-indicated—in fact, I can say, markedly contra-indicated. On the other hand with the second case the administration of diamidine-diphenoxypentane t.d.s. led to an immediate rise in the Hb, B.P., E.S.R., W.B.C., O.U.T.C. and All, and an equally dramatic fall in the cost of living (for pathological report on P.M. vide appendix). The third case revealed remarkable features, for no-one[1 17 29 42 117] has yet reported a case of Generalised Osteitis Fibrosa Cystica *complicated by odontalgia and a mother-fixation in an oncologist*. An uneventful recovery from all three complaints followed the exhibition of forceps.

Good stuff that. Not only is there a lot to be said for clear and sparkling English but you can say quite a lot in it; and some of the words go a long way to fill up the lines. To my mind they have $\pm 1{\cdot}23$ and $P > {\cdot}05$ beat to a frazzle.

* * *

Our two obstetric registrars have become engaged to each other. It has been decided that unless two locums can be obtained before their wedding at the end of this month they will have to spend their honeymoon *independently*.

* * *

I wonder if all travellers by air to the Continent suffer from the same after-effects as I do. Not the reactions after unaccustomed French cooking—not an over-emphasis of reminiscence of that *Poulet de Bresse* in Montmartre; not the *Quenelles* at Auxerre (and who could possibly imagine that a muddy river fish could be reincarnated by the French art into such morsels of fairy-like consistence and ethereal flavour?); not the noble *Chateaubriand* in the restaurant near Les Invalides. No, what I am thinking of is the new world in which I am living owing to the rejuvenescence of my eustachian tubes. It is twenty-five years since my ear-drums have had to acclimatise themselves with such rapidity to an altitude of 5000–6000 feet. Persistent swallowing on the way up and blowing of the nose on the way down, have not achieved the elasticity necessary to the hardened air-traveller. So now I live in a world of clatters and bangs. That crack of thunder? Merely a yawn. That drumming of heavy rain on a corrugated roof? The sound of chewing rather tough French beans. That rocket anti-aircraft battery opening up? I blew my nose over-enthusiastically.

I suppose that I ought to be able to prescribe a cure for myself; but there is no doubt that the logical one is the attractive one. My tubes clearly need acclimatisation to modern conditions. How can that be better achieved than by a fairly frequent, say once a week, transcontinental air-trip? A medical certificate to that effect—and who knows better how to write that kind of thing? But I wonder whether the foreign exchange department of the Bank of England would be prepared to play.

* * *

Dear Messrs. Guinness,—In case your Kinkajou falls ill or looks pale, I thought you ought to know that its normal red-cell count is 6·52 million per c.mm. and its differential count usually shows about 15% of eosinophils (Wintrobe, M. M. *Clinical Hematology*, p. 819). The view that its blood-cells are upside-down is mere folklore.—WELL-WISHER.

Letters to the Editor

SELECTION OF MEDICAL STUDENTS

Sir,—In his letter of Sept. 13 Prof. Samson Wright has posed an interesting problem: how many applicants are there each year for the 2700 places in our medical schools? Owing to the large number of multiple applications this question cannot be easily answered for the whole country, but it may be of interest to report the preliminary result of a survey of the applications made in 1951 to the twelve London medical schools. The accompanying table expresses the salient facts.

APPLICATIONS FOR PRECLINICAL ENTRY IN 1951 TO THE TWELVE LONDON MEDICAL SCHOOLS

—	(1) No. of applications	(2) No. of candidates	(3) No. of candidates accepted by at least one school expressed as a percentage of col. (2)
Men :			
Applying at one school only	999	999	*29*
Applying at 2–4 schools ..	1983	704	*31*
Applying at 5 or more schools	2960	464*	*38*
Total	5942 (av. 2·74 per candidate)	2167	*32*
Women :			
Applying at one school only	325	325	*27*
Applying at 2–4 schools ..	804	289	*39*
Applying at 5 or more schools	882	138	*53*
Total	2011 (av. 2·67 per candidate)	752	*37*

* Including one (unsuccessful) candidate who applied at all twelve schools.

The figures show that on the average each candidate applied to between two and three schools (there being little difference between men and women in this respect), and that the proportion who were finally successful was just under 30% for those who applied once and increased with a greater number of applications. The precise significance of this increase is not apparent; for no distinction is made between the candidates who (either through zeal or caution) applied simultaneously to a number of schools, and those who made successive applications after successive failures. The other limitation of the first year's results is that we do not yet know how many of the unsuccessful candidates of one year try again (and are possibly accepted) in the next. Not until the scheme has been running for at least three years will it be possible to give a complete picture of what is happening.

This survey was initiated by the Conference of Deans of the Metropolitan Undergraduate Medical Schools, who have authorised me to publish this account. As the first year's work was largely experimental it is not proposed to publish a full report, but I have a few copies left of a stencilled summary.

Department of Medical Statistics,
St. Bartholomew's Hospital,
London, E.C.1.

M. P. CURWEN.

THE TRENDELENBURG POSITION

Sir,—I should like to comment on some aspects of Mr. Howkins's article last week.

In the first place, the gynæcologist's view of the Trendelenburg position is well expressed by his summary that "it should be safe for the patient and comfortable for the surgeon and his assistants." I would venture to suggest that the anæsthetist's view differs slightly from this, since he regards it as a physiologically bad position which should be used as little as possible. It is recognised that in a conscious patient a 90° head-down tilt is fatal within a few hours, death being preceded by most intense agony—a fact well known to the Inquisition in the 13th century. The usual 30° Trendelenburg slope applied to the anæsthetised patient causes a rise in blood-pressure, œdema of the head and neck, chemosis, and congestion of the cervical veins. It also reduces the vital capacity by 15%, mainly by upward displacement of the diaphragm, quite apart from the additional effects of abdominal packs and retractors. The photographic department of St. Bartholomew's Hospital has provided me with an excellent set of photographs showing clearly the alteration of contour of the abdomen and thorax with the progressive rise of the diaphragm in increasing slopes. The moral of this is that at the end of operation the tilt must be reduced in at least two stages, and the inevitable collection of secretions in the nasopharynx removed by suction before the tracheal tube is withdrawn.

The question of maintenance of the Trendelenburg position has occupied me for a considerable time; shoulder-rests alone are most unsatisfactory and have produced brachial plexus palsy, even if the arms are not abducted. Ogier Ward's pelvic rests avert this but cause bunching up of the anterior abdominal wall and must not be used alone, as heavy patients tend to slip. Even experienced orderlies cannot always make certain that these rests are secure, as there is insufficient leverage on the spanners provided to make the nuts really tight. I have twice seen patients slip with this device; and shoulder-rests, just clear of the shoulders, should always be used as an additional precaution. It is possible that the Hans modification may prove safer in practice.

It has long appeared to me desirable to employ friction as a retaining force, and I have been well pleased by a prototype 'Sorbo' mattress covered with a corrugated rubber sheet (sewn on by the senior resident anæsthetist!). This mattress is strapped to the horizontal bar under the operating-table supporting the hinge of the leg-rests, and consequently cannot itself slip on the table-top. If the patient's bare skin rests on the corrugations, the considerable area of the buttocks and scapula region in contact with them will hold the average patient to a tilt of about 30° without slip. Shoulder-rests must be in position as a secondary precaution, and it must also be realised that if the patient's skin becomes wet, from perspiration or fluid from a ruptured ovarian cyst, the coefficient of friction will be much diminished. I do feel most strongly that the legs must be kept straight, and the usual thick sorbo strip placed under the tendo Achillis (not the heels) to avoid compression of the calf veins.

I think I have said enough to indicate that a high Trendelenburg tilt is not the innocuous position sometimes supposed, and I have personal knowledge of a patient who woke up blind from a retinal detachment after a hysterectomy performed with an exceptionally steep tilt.

A "NEW" BLOOD-GROUP CHARACTER RELATED TO THE ABO SYSTEM

Sir,—I have read with great interest the paper by Drs. Bhende, Deshpande, Bhatia, Sanger, Race, Morgan, and Watkins in your issue of May 3, a reprint of which I have just received from Dr. Race.

For several years before the war I searched for the type of blood described by these authors, being certain that it must exist. Despite several thousand tests the result was negative. During the war, when I was obliged to live in the Warsaw ghetto, chance helped where planned investigations had failed. Having difficulties in determining the blood-group in a case of

Hodgkin's disease (in a Jewish woman, who died two weeks later), a bacteriologist asked me to resolve them. The tests, performed in the kitchen of my provisional home with my assistant Róża Amsel, revealed the coexistence of unagglutinable (by any test serums) erythrocytes and strong anti-O agglutinins in the serum of the patient. The titre of the agglutinins was 1/32, the thermal amplitude reached 30°C. With this serum it was possible to demonstrate differences in the O-substance of different O-erythrocytes. It could not be proved whether there was an inherited character of the blood or whether the unusual finding was due to the loss of the O-agglutinogen. In our paper, which could be published only when the Nazi occupation of Poland ended in 1946, the existence of pleiades was discussed.[1] This paper ends with the following words:

> "It is necessary to take into consideration such types of blood in seroanthropological work, because they can eventually indicate the first occurrence of blood factors which are associated with genetic factors."

These observations were made in 1941 with my assistant, the late Róża Amsel. Unfortunately she was unable to live to see the published paper: she was murdered in 1943, during the extermination of all Jews in Warsaw.

FUTURE OF THE OCCUPATIONAL HEALTH SERVICES

SIR,—The leading article in your issue of Oct. 11 contains much interesting matter. I should like to select one or two points for comment.

1. Referring to the paper by Prof. I. G. Davies it is suggested that a preventive health service for work-places could be provided by "fusing" the duties of the medical inspector of factories, the appointed-factory doctor, and the medical officer of health. Each of these three has a very full job. What is meant by "fusing," and to whom is the "fused" control to be handed?

2. It is suggested that at local level the medical officer of health and his staff, assisted by the A.F.D. and local factory inspectorate, should be made responsible for detailed enforcement and maintenance of health standards. What will then be the position of the medical inspector of factories in relation to the medical officer of health? The local authorities are busy people and not many have extensive experience of factories: their staff would have to be augmented. Why not augment the staff of the medical inspectorate of factories where the experience now lies? The main handicap at present would appear to be shortage of staff to enforce standards and give advice. A large part of the work is educational.

3. Dr. Nash is credited with the suggestion that the precedent of the Public Health Laboratory Service might be followed in setting up an Occupational Laboratory Service. It is true that fewer laboratories would be needed, but it is hard to see how public-health laboratories could be used or adapted. The training, the technique, and not least the apparatus required are very specialised: staff and laboratory space would have to be separate.

Perhaps one laboratory in each region might suffice. Is it not worth considering attachment to a university department of public health or occupational health where experience and apparatus could be made available for postgraduate training? This is in fact what has been done by the London School of Hygiene in conjunction with the Slough Industrial Health Service, and it appears to be a useful example.

Community Centre,
Farnham Road,
Slough, Bucks.

M. E. M. HERFORD.

*** We think that the service provided, as Professor Davies puts it, by "fusing" the duties of the medical inspector of factories, the appointed factory doctor, and the medical officer of health should be controlled by a central Government department. The medical inspector of factories would advise, coöperate with, and if necessary direct the medical officer of health in his duties connected with occupational health. The medical inspectorate of factories should certainly be augmented, as Dr. Herford implies; but it could not carry out the day-to-day work in the factories. Regarding the laboratories, it might be more economical to use existing buildings; but, as we said, it would be necessary to "adapt" them, thus satisfying the conditions mentioned by Dr. Herford. All laboratory work is specialised; that relating to occupational health is not unusual in this respect.—ED. L.

OTITIS EXTERNA

SIR,—Your annotation of Oct. 11 gives the impression that you regard this condition as an infection with, perhaps, an "active underlying dermatosis." In the majority of cases seen in this country otitis externa is an eczema of the external auditory meatus, and it is often accompanied by eczema in other parts.

The concept of "eczema" has by no means been clarified by the introduction of more modern terms like seborrhœic dermatitis, atopic eczema, and exudative neurodermatitis. But it is worth while to remember the words of Sir Archibald Gray[1] in his Harveian Oration, that

> "The relation of pyogenic infection to skin eruptions has presented great difficulties, especially in eczematous conditions. A moist lesion on the skin is, in fact, a living culture tube and it follows that any of the organisms grown from such lesions may be only saprophytic. It is extremely difficult under such conditions to determine the ætiological significance of pyococci."

In the treatment of external otitis it seems reasonable to employ a suitable antibiotic systemically where there are manifestations of secondary infection, such as lymphangitis, lymphadenitis, cellulitis, furunculosis, and erysipelas, and topically for a limited period with the defined objective of reducing a heavy secondary contamination.

On the other hand, the routine prescription of antibiotic ear-drops or ointment, directed with the best intentions against the sensitive organism, will often excite another type of sensitivity—an allergic hypersensitiveness of the epidermal cells—and a dermatitis medicamentosa will result. The wise physician, therefore, will continue to rely on preparations, such as weak aluminium acetate or silver nitrate solution, which have stood the test of time, along with other measures directed at the relief of eczema, such as physical and mental rest.

London, S.W.2.

MICHAEL FEIWEL.

THE NOTIFICATION OF DISEASE

SIR,—I read with considerable interest and pleasure the article by Dr. E. D. Irvine (Oct. 11). I wish to offer no more than some stray reflections on scarlet fever.

Scarlet fever is still classed as a disease in its own right—partly as the result of tradition and history, and the fact that in "the old days" it was a serious disease. Now we know that scarlet fever is simply a streptococcal sore throat in which the bacterial exotoxin happens to include an erythrogenic factor. But hæmolytic streptococci can be equally virulent and infectious whether or not a rash occurs.

One wonders whether there should be any difference in the preventive measures taken in connection with the two conditions. I appreciate that there are practical difficulties relating to streptococcal sore throat which do not apply to scarlet fever. Yet the diagnosis of scarlet fever *may* mean isolation in a hospital, whereas a streptococcal sore throat is perhaps treated by means of chemotherapy until the temperature is normal and the throat clean. I would not go so far as to say that scarlet fever is today a medical anachronism; but there would appear to be a prima-facie case for reconsidering, and possibly reorientating, our measures in respect of these two types of streptococcal infection.

CAROTENÆMIA

SIR,—The interesting article by Dr. McConaghey (Oct. 11) contains statements which should not pass without comment.

Up to the present time, in this country we have expressed the carotene and vitamin-A levels in international units (I.U.), though abroad there is a growing tendency to use the decimal system for this purpose. Both the carotene and the vitamin-A levels are somewhat dependent on the standard of nutrition and are subject to slight seasonal influences. But the normal levels cited by Dr. McConaghey for serum-carotene (240 mg. per 100 ml.) and for serum-vitamin-A (70–160 mg. per 100 ml.) are certainly based on considerable misunderstanding. Our latest published normal figures for the London area were total carotenoids 153 I.U. (91·8 µg.) and vitamin A 121 I.U. (36 µg.) per 100 ml.; and these figures are closely comparable with figures found by others and quoted by us.[1]

London, W.1. Z. A. LEITNER.

WITHDRAWAL OF TEACHING

SIR,—Your admirable article (Oct. 11), on the damage done by the withdrawal of the C.O.I. mobile units and the Crown Film Unit, deserves the full support of all those using films in medical education.

Cinematograph equipment is costly, and the time and labour involved in film production much greater than is generally realised. All this, however, is justified because the results can be shown to audiences all over the country—not only today, but for as long as the subject remains of interest. Thus, any step which tends to restrict the showing of films will increase the cost relative to each individual viewer. The acquisition of a projector by an organisation which is not constantly showing films is an expensive business; and as in most cases a trained projectionist is not available, not only is it costly but the results are crude and amateurish.

It is even more in the field of film production that a trend against centralisation needs to be resisted. Many hospitals possess expensive cameras which are little used. Finance boards which have spent £500 on a ciné camera consider that they have treated their photographer lavishly. In fact they have merely provided him with an instrument that will consume raw film at an appalling rate. Without the rest of the paraphernalia of film-making, the expenditure of much labour, and the exercise of considerable experience, the photographer can only produce some very crude material for a proper teaching film. The use of this unfinished material, and the belief that it fulfils the possibilities of the film in education, is doing more than any other factor to discredit this valuable teaching aid.

The position, then, is that much capital equipment is uselessly scattered among hospitals and institutions while money is frittered away on poorly produced films, whose quality debars them from being shown outside their own home circle. If money is to be spent economically it must be at a higher level than in individual hospitals or medical schools. Only then will there be sufficient capital resources to produce films of a technical standard that will command a wide distribution.

This does not imply that hospitals should be discouraged from making films. On the contrary, they would be able to draw on any items of specialised equipment that they required, with the help of experienced film technicians to guide them where necessary.

Medical films are in some ways more difficult to make than any others. It is thus all the more important that we should husband our resources and use them to the best advantage, instead of scattering them to the four winds.

[illegible] Department,
[illegible] School, PETER N. CARDEW.

PULMONARY COMPLICATIONS OF INFLUENZA

SIR,—I have found, as a matter of experience, that whenever I encounter the word "entity" in medical literature, I have to stop and read the sentence in which it occurs, together with its immediate context, several times in an attempt to find out what information the author was trying to convey to his readers. Sometimes, I confess, I am baffled in this attempt, for the word is a favourite with those who have not succeeded in clarifying their thoughts but are nevertheless determined to put them into print. Scarcely ever does the sentence make sense if for "entity" is substituted its dictionary meaning.

Now, as far as I can recall, I have never used this metaphysical smoke-screen of a word in print, and certainly it does not occur in my paper mentioned in your annotation last week on pulmonary complications of influenza. Yet in that annotation I am represented as having thought that "influenzal pneumonia is a distinct entity, differing clinically from other forms of pneumonia." I am so puzzled by this that I should like to use a little of your space (and, I hope, of the time of some of your readers) to set out clearly what in fact I did in the investigation mentioned, and what were the conclusions reached.

In the first considerable epidemic of influenza in London after the discovery of the influenza virus, I studied all patients admitted to Hammersmith Hospital with good evidence of a recent or present influenza infection. Having defined the group to be studied on the basis of an association with epidemic influenza, I studied especially those patients who showed evidence of lung changes, enlisting the generous aid of my colleagues in the departments of bacteriology, hæmatology, and morbid anatomy. The data so obtained were finally analysed to determine in what respects, if any, the lung changes observed differed from those found in acute lung infections not associated with influenza; and, especially if such a difference were observed, what part the virus was taking in the causation of the lung changes.

The chief feature of the clinical picture was its variability from case to case; and the general conclusion reached about the causation of the lung changes was that "the influenza virus can produce severe changes in the lung in man which facilitate invasion by bacteria. The course of the disease depends upon the extent and virulence both of the virus and of the bacterial infection; the extraordinary variability of the clinical picture is due to the numerous possible combinations of these factors." Thus the cases studied were found to be an ætiologically defined group only in a very limited sense, that of being related temporally to an influenzal infection. Microbiologically, their ætiology was found to be mixed, both the virus and a variety of bacterial types being concerned in the production of the lung changes, so that it is only in a sense so modified as to be trivial that they could be called from this viewpoint "a distinct entity."

Clinically, it is true, I noted that, viewing the cases with consolidation as a group, certain differences could be detected from the features usually associated with simple pneumococcal pneumonia; but the degree of this difference varied greatly even among the cases with lobar consolidation, and the whole group differed from case to case so greatly that it was necessary to divide it for description into no fewer than five subgroups. I should certainly hesitate to suggest that in an isolated case (with the possible exception of the acute fulminating variety) it would be possible to deduce a relation to influenza on the characteristics of the pneumonic stage alone. I do not see how that statement "influenzal pneumonia is a distinct entity" can be construed, even with the greatest ingenuity, so as to convey the modest but clearly expressible conclusions of my clinical study. All it conveys to me is that you are aware that I once wrote a paper relevant to the subject of your annotation.

EFFECTS OF LEUCOTOMY

SIR,—Your annotation last week says of me, in reference to a book that I wrote on this subject: "He provided a mass of interesting clinical data, but . . . did not even add up the number of patients in each diagnostic group."

Of course I added these up (many times, since I am bad at arithmetic). The numbers of cases in the largest diagnostic group and its main subgroups are given in a table facing p. 352, while those in its further subgroups are on pp. 230–231. The numbers in all the other groups are given in the text of the appropriate chapters, and are repeated in the summaries that conclude them.

As many more people will read the annotation than will be familiar with the book, perhaps you will be good enough to publish this gentle reproach in correction of your mis-statement.

London, W.1. MAURICE PARTRIDGE.

BUTAZOLIDINE

SIR,—The early reports on butazolidine [1–3] were so favourable that it immediately began to be widely used; and in the British Isles alone about 100,000 patients are said to have received this drug.[4] The first warnings that butazolidine is not so free from serious toxic effects as was at first supposed have already appeared.[5–7] In the small series of cases that we have treated we have been impressed by the frequency of toxic reactions; and we report here a case of jaundice and agranulocytosis in a patient, to whom butazolidine was administered.

The patient, a housewife, aged 66, was admitted to this hospital on July 25, having had generalised muscular pain for the previous 6 weeks; her earlier medical history was uneventful. She was somewhat obese, with tenderness of muscles, especially round the elbows, knees, and shoulders, limiting all movements. There was no evidence of joint involvement. The blood-pressure was 185/120 mm. Hg. Initial investigations showed hæmoglobin 76% (11·25 g. per 100 ml.); white blood-cells 8350 per c.mm. (polymorphs 55%, lymphocytes 39%, eosinophils 2%, monocytes 4%); erythrocyte-sedimentation rate (E.S.R.) 93 mm. in first hour (Westergren). Radiographs of knee-joints showed mild arthritic changes. The urine was normal. Generalised fibrositis was provisionally diagnosed.

Heat treatment was started, but after a week the patient's condition was unchanged. In view of this, and the persistently raised E.S.R. (now 115 mm.) it was thought that the disorder might be early rheumatoid arthritis. The possibility of an infective arthritis was also considered, since radiographs showed apical abscesses in two teeth in the lower jaw. On Aug. 12 eight teeth were extracted under nitrous oxide anæsthesia with penicillin cover. For the next 2 days the temperature was somewhat lower, and the patient's condition rather better.

On Aug. 22 administration of butazolidine was begun in a dosage of 1·2 g. per day by mouth, and the patient was put on a low-salt diet. Within 36 hours her condition had improved notably, and during the next 10 days movements were almost painless. At the end of this time a maculopapular rash appeared on the face, and shortly afterwards slight œdema of the ankles was noticed. On Sept. 2, therefore, the dosage of butazolidine was reduced to 0·6 g. per day. After 2 days the rash, though fading, was still present and the skin of the legs was desquamating. During the next 4 days the patient complained of feeling ill and depressed; her temperature was about 101°F and she had developed mild bronchitis. On Sept. 8 jaundice was evident, and butazolidine was immediately discontinued, a total of 16 g. having been given.

Within 2 days the temperature had fallen to 99°F; but the patient now felt drowsy and had anorexia and nausea, and the jaundice had deepened (serum-bilirubin 6·4 mg. per 100 ml.). The liver was tender but not enlarged; the urine contained bile, but the fæces were normal.

Drowsiness persisted, and on Sept. 15 the hæmoglobin was 66% (9·77 g. per 100 ml.); white blood-cells 2450 per c.mm. (lymphocytes 88%, monocytes 12%, polymorphs nil). Her temperature had now risen to 102°F with two rigors. She was therefore given aureomycin 0·5 g. 6-hourly by mouth; there was no further rigor, but the temperature did not fall. There was no purpura or stomatitis.

On Sept. 18 the jaundice was more pronounced, and the patient was extremely ill. A blood-count showed hæmoglobin 56% (8·29 g. per 100 ml.); white cells 2050 per c.mm. (lymphocytes 94%, monocytes 6%, polymorphs nil); platelets 105,000 per c.mm. The sternal marrow was found to be very poorly cellular, and the few polymorphs present showed pronounced toxic changes; the appearances supported a diagnosis of agranulocytosis (see table).

One pint of fresh blood was transfused; and on Sept. 19, on Dr. A. Piney's advice, the sternum was opened under general anæsthesia and packed with marrow obtained earlier that day from a rib during a thoracotomy on another patient. Two further pints of stored blood were transfused immediately after the operation. A biopsy specimen of marrow obtained at the operation showed some improvement; the marrow was moderately cellular, but segmented neutrophils were extremely scanty.

After operation the patient recovered rapidly. On Sept. 24 the jaundice had disappeared; and apart from a sacral bedsore the patient was well on the road to recovery. Marrow from the iliac crest was found to be moderately cellular; the granular series had reverted to normal, but erythropoiesis seemed still to be somewhat depressed; the myeloid-erythroid ratio was 17 : 1 (see table). Since then in periodic films of peripheral blood the white-cell series has been normally differentiated. The patient has remained well.

This case is of special interest since the patient was in hospital without treatment, apart from heat and tab. codein. co., for 4 weeks before treatment with butazolidine was started. We also confirmed from the patient's general practitioner that he had administered no drugs that are known to produce agranulocytosis; and the patient herself denied taking any drug unbeknown to her doctor. We therefore feel that the agranulocytosis can only be ascribed to the butazolidine. It is noteworthy that the granulocyte-count improved rapidly after the drug was discontinued; and we do not feel that the small amount of marrow implanted at operation contributed materially to this change.

We informed Messrs. Geigy Ltd. the manufacturers; and they kindly arranged for Prof. R. Domenjoz, of

Basle, to examine the case. He, like the manufacturers, had heard of no similar case.

We suggest that butazolidine should be regarded as a dangerous drug, and that 1·2 g. per day is probably a dangerously high dosage. Before treatment with butazolidine a white blood-cell count should, we suggest, be made; and further counts should be made at least weekly while this treatment is continued. Any definite fall in the number of polymorph cells is, in our opinion, a contra-indication to further butazolidine therapy.

When the case of agranulocytosis reported here was discovered a routine white blood-cell count was made on all our patients receiving butazolidine. One patient had a relative granulopenia (44%) with a total white blood-cell count of 6200 per c.mm. When butazolidine was discontinued the count rose rapidly to its previous level of 74% granulocytes in a total of 12,400 white blood-cells per c.mm.

We wish to thank Dr. Kenneth Playfair, under whose care the patient was admitted, for permission to report the case described here; Dr. A. Piney and Dr. M. S. Ross, who made the sternal punctures and marrow-counts; and Mr. Roy Parkinson, who implanted the marrow.

Queen Mary's Hospital,
Stratford, London, E.15.

D. L. CROWTHER
F. R. M. ELGOOD.

SIR,—With reference to the recent correspondence on the toxic effects of butazolidine, I would like to report the following case.

An unmarried woman, aged 59, had had rheumatoid arthritis for 20 years. She had never had gold injections or any treatment other than spa therapy. She had not been taking any analgesics or "antirheumatic" compounds.

On Sept. 15 her general practitioner started her on a course of butazolidine, 1·2 g. daily by mouth. As soon as she began to take these tablets she got quite severe indigestion, and on the 3rd day she began to get breathless. After 7 days she gave up taking the tablets because abdominal pain and nausea were severe.

On Sept. 23 a maculopapular eruption appeared on her face and lower abdomen; some septic spots appeared all over her body a few days later. On Sept. 25 her left breast became inflamed, and cellulitis developed with enlarged axillary lymph-nodes. This area became extremely painful.

On Sept. 30 her throat became dry and sore. This got progressively worse, and on Oct. 7 it was so bad that she was unable to swallow anything at all.

When admitted to hospital, on Oct. 7, she was very ill with a temperature of 103°F. She had very severe stomatitis and pharyngitis; her mouth and tongue were covered with a thick growth of yeasts. She had moderately severe bronchopneumonia, and her lips were slightly cyanosed. There were several peculiar tender red swellings on her left arm, resembling erythema nodosum. The cellulitis of her breast was quite extensive, and she had several septic spots scattered over her body. Her rheumatoid arthritis was moderately severe, but she had been able to walk satisfactorily before her illness.

Investigation of the blood gave the following results: white cells 4000 per c.mm. (neutrophils 4%, eosinophils 0%, basophils 1%, lymphocytes 40%, monocytes 11%, myelocytes 3%, metamyelocytes 41%); platelets 250,000 per c.mm.; hæmoglobin 72%; red cells 3,630,000 per c.mm.; erythrocyte-sedimentation rate 112 mm. in first hour (Westergren). Sputum grew a mixed culture of *Staphylococcus aureus*, yeasts, *Streptococcus viridans*, and a few hæmolytic streptococci of Lancefield's group A. All organisms except the yeasts were sensitive to all antibiotics in common usage.

The patient was treated with aureomycin, penicillin, pentose nucleotide, and pyridoxine. Within 18 hours her temperature had fallen to 99°F, and it has remained in this region ever since.

A further white blood-cell count on Oct. 9 showed a total of 20,000 per c.mm. with 44% mature polymorphs, 22% lymphocytes, and 28% metamyelocytes. Her general condition has improved remarkably and she is now taking solid as well as liquid foods. The yeasts have been eliminated by painting the mouth with gentian-violet.

There can be no doubt that this patient's symptoms have all been due to butazolidine therapy; and it would therefore seem that routine blood-counts should be done on all patients receiving this drug.

I am grateful to Dr. Geoffrey McComas for permission to publish this case.

Croydon General Hospital. D. J. A. JARVIS.

SIR,—A patient with rheumatoid arthritis whom I was treating with butazolidine developed a temperature of 104°F with a widespread maculopapular rash and severe neutropenia. This occurred after the second injection of the drug.

Dewsbury. GODFREY B. TAIT.

TREATMENT OF BRONCHIAL CARCINOMA

SIR,—Your excellent leading article of Sept. 27 makes no mention of wheezing as an early symptom of bronchial carcinoma. In our experience wheezing is a symptom of the greatest importance, the significance of which is very commonly overlooked. It results from partial bronchial obstruction, and often disappears when the obstruction becomes complete.

A wheeze, or "bronchitis," occurring *for the first time* in a patient over 35 years of age is sufficient ground for a full clinical and radiological examination, supplemented by bronchoscopy. The finding of a *persistent* localised rhonchus on auscultation is of the utmost significance.

Surgery,
ospital

CONSTANCE M. HESLING
GORDON CRUICKSHANK.

THE HERXHEIMER REACTION

SIR,—Your annotation last week is inaccurate in stating that "it fell to Herxheimer to describe the untoward effects of the drugs invented by his fellow-countryman, Ehrlich."

The reaction was first described by Prof. O. Jarisch (1850–1902) in 1895 and was observed during treatment with mercurial inunctions. An exacerbation of a syphilitic roseola eruption was noted during the first few days of a course of mercury.[1] Dr. Karl Herxheimer and his assistant, Dr. Krause, reported in 1902 similar reactions in sixty patients "twenty-four hours after an initial inunction of 40 g. of grey mercurial ointment."[2]

London, W.1. A. H. HARKNESS.

DEVELOPMENT OF TUBERCULOSIS IN CONTACTS

SIR,—Dr. Aspin's interesting paper[3] raises a question often left unanswered. How does the time taken for the infection to develop fit in with our ideas about the pathogenesis of the disease?

A positive tuberculin reaction in early childhood remains positive until puberty and for many years after. Such people do not become contact cases of tuberculosis after puberty unless they are further infected. Negroes are susceptible at an earlier age because of their earlier development.

Has physiological puberty anything to do with this phenomenon? The superinfection necessary to produce active tuberculosis occurs only in certain circumstances of stress unpredictable in adult life.

Dr. Aspin found that the first year after contact yielded 22 times as many infections as the average incidence in the general population would suggest. Thus the usual case of tuberculosis discovered among contacts and in the general population had been in contact with a newly notified case of tuberculosis for one year or less. This original contact case was almost certainly *clinically* negative before contact, and yet developed pulmonary tuberculosis of adult type within a year.

It would be possible to find out how long the newly notified case had had symptoms suggesting infectivity before being

iagnosed and *notified.* This *time would then have to be* dded to give the probable interval between primary infection nd established adult disease.

Will this time suffice for the primary complex to levelop through the secondary stage into the adult ype? It is difficult to understand how this theoretical ourse can be run in so short a time unless the three hases overlap very considerably.

An answer to this question would help to solve the roblem defined by Dr. Aspin—"the periodic review of ertain groups of originally healthy contacts, in the iope of picking out for treatment persons on the point f falling ill."

PNEUMA, PSYCHE, AND SOMA

SIR,—In his thoughtful paper of Oct. 11 Dr. George ay quotes Plato's famous parable of the driver and his air of horses. May I point out, for those who would efer to the context, that the passage is to be found; iot in the *Phaedo*, but in the no less profound and eautiful dialogue *Phaedrus* (pp. 246–254, Stephanos).

Cambridge. G. CYRIL ARMSTRONG.

CLINICAL TESTS OF TRICHLORETHYLENE INHALERS

SIR,—In response to a recommendation of the Working Party on the Recruitment and Training of Midwives, the Medical Research Council appointed a Committee on Analgesia in Midwifery to satisfy itself that a trichlorethylene inhaler could be designed which was safe for use by midwives in domiciliary practice.

Preliminary trials suggest that trichorethylene, when administered in new inhalers designed to a performance specification drawn up by the committee, is both safe and effective in normal labour.

A sufficient number of the inhalers is now available for more extensive trials, which are being organised, in coöperation with the Central Midwives Board, by a joint subcommittee of the Committee on Analgesia in Midwifery and of the Anæsthetics Committee of the Royal College of Obstetricians and Gynæcologists. The trials have been planned to include the use of the inhalers in domiciliary practice, by midwives, for selected patients who are expected to have an uncomplicated labour. Certain local health authorities have agreed to take part in these trials, which are being carried out also in hospitals.

General practitioners whose patients would be suitable for inclusion in the trial are being asked, in each case, for their permission. The Medical Research Council will be most grateful for the coöperation of the profession in carrying out these trials.

GEOFFREY ORGANE
Secretary, Medical Research Council
Committee on Analgesia in Midwifery.

ACUTE AGRANULOCYTOSIS AND THIOSEMICARBAZONE

SIR,—In my article (March 1) on *p*-acetamidobenzaldehyde thiosemicarbazone in the treatment of leprosy, I recorded that in 126 cases treated for periods of up to seventeen months, 1 case of acute agranulocytosis attributable to this substance had been seen. In this group of patients, now numbering 150, I have had 2 more cases of acute agranulocytosis.

A young African man in good physical condition, with mild leprosy, started T.B.1 treatment on Feb. 9, 1952; the dosage was 50 mg. a day for one week, 100 mg. a day for the second week, and 150 mg. a day for the third week. On the twenty-second day of treatment he felt unwell and feverish in the evening, and next morning he reported with a temperature of 101°F. Malaria was suspected, but a blood-film revealed acute agranulocytosis. T.B.1 was stopped, and 1 million units of penicillin was given and was repeated daily until recovery. 'Pentnucleotide' was not available.

That afternoon the temperature rose to 105°F. There was no serious inflammation of the mouth or throat; there was a small septic focus on one foot at the site of a cut, and later a similar focus appeared on one hand.

High remittent fever continued for seven days, reaching its maximum 106·2°F—on the second day and then slowly subsiding. No serious local inflammation developed anywhere, and the general condition of the patient remained excellent. The spleen became palpable on the fourth day. Apart from the high fever no serious symptoms developed. Blood-culture was not possible here.

The white-cell count began to rise greatly within eight days, with signs of intense bone-marrow activity; from the seventh day many myelocytes and metamyelocytes were seen in the blood-films. The number of white cells per c.mm. before treatment and on the first ten days of the illness were as follows (granulocytes in parentheses): before treatment, 6500 (3185); day 1, 1800 (180); day 2, 1300 (106); day 3, 1900 (143); day 4, 2300 (115); day 5, 2000 (40); day 6, 4200 (428); day 7, 8500 (2550); day 8, 10,000 (5230); day 9, 10,400 (6184); day 10, 17,900 (12,942).

Of the clinical features, the very high fever in the absence of any local signs of infection was striking. The prompt diagnosis and penicillin treatment almost certainly prevented serious local inflammation in the mouth, throat, and elsewhere.

The second case was similar, but was complicated by an acute suppurative lymphadenitis in both groins.

Both these cases and the case previously recorded occurred during the first month of treatment; but many of our patients have received two years' treatment without trouble. It appears possible that agranulocytosis occurs early or not at all. Some workers have suggested that it is an allergic rather than a toxic phenomenon.

These further cases confirm the view previously expressed that T.B.1 treatment should be given only under close medical supervision. If any fever develops, particularly during the first few weeks of treatment, agranulocytosis should be suspected and the blood examined. With prompt diagnosis and energetic penicillin treatment, recovery may take place in about a week; for it appears that if serious infection can be prevented or controlled, the agranulocytosis will look after itself.

Uzuakoli, East Nigeria. JOHN LOWE.

Parliament

Experiments on Animals

IN the House of Lords on Oct. 14, Lord DOWDING, speaking on surgical and medical experiments on animals, declared that the law designed for the protection of animals against cruelty was gravely defective. There was neither adequate inspection nor proper enforcement. The experiments were excessive in number, repetitive, and often unpractical when it came to applying them to human maladies. Laymen had no access to the laboratories and the evidence was incomplete and restricted to accounts given by the experimenters themselves in medical and scientific journals. It was not unreasonable, he thought, to assume that the actual situation might be a good deal worse than was shown by the available evidence. The number of experiments had increased from 300 in 1876, when the Cruelty to Animals Act was passed, to over 1,750,000 in 1950. Yet the number of inspectors had only been increased from 2 to 5. He was greatly perturbed by a new form of animal *exploitation* which had caused vivisection to take a secondary place. He referred to the use of animals in the manufacture and testing of many modern drugs. Apart from the use of calves for the production of smallpox vaccine, animals were also used in testing insulin, suprarenal hormone, thyroid, and pain-killing drugs. Surely, Lord Dowding said, it should be possible to substitute chemical and mechanical tests for this traffic in flesh and blood. He asked the Government to make an official inquiry into this question, which had not been touched by earlier legislation. He also asked for a stricter enforcement of the Act of 1876.

Lord HAILEY did not believe that the scientific world would object to an inquiry if necessary, and it was admitted that in some respects the Act was out of date and might need amendment. But he feared that an inquiry might once more stimulate the energies of the anti-vivisection societies to advocate the total abolition of all forms of animal experiments, with the result that science would be deprived, not merely of the means of achieving advance in physiological science, but also of the means of testing and standardising new drugs. That was a danger which the scientific world would deprecate.

Lord WEBB-JOHNSON said he was in complete sympathy with Lord Dowding in his anxiety that proper precautions should be taken in the issue of certificates for experiments on animals, and for eight years as president of the Royal College of Surgeons he had refused to sign many applications for licences, either because the experimenter was not working under satisfactory conditions, or because the experiment had been repeated a sufficient number of times to prove that the results obtained were established as facts. His visits to other countries had satisfied him that the precautions taken here were stricter than those in any other country of the world. He himself believed that the British safeguards were sufficient.

The EARL OF SELKIRK pointed out that the Act of 1876 was unique in the sense that no other country in the world had an Act of that character. It provided that no experiments on living vertebrates might be carried out except under stringent conditions. Such experiments might be carried out only for definite purposes—i.e., for the acquisition of knowledge useful in the saving of life or the alleviation of suffering—and not for training or practice. Before anyone obtained a licence he required two signatures, one from the president of a learned society, and the other from a professor of a branch of medical science. Under the licence given the animal must be anæsthetised during the whole operation; and if the pain was likely to continue after the anæsthetic ceased, the animal must be killed before recovery. Experiments could be carried out only in registered places, and full records must be kept and annual reports submitted stating the number and nature of the experiments performed. These places were, of course, open for inspection at all times. The duties of inspectors were to visit regularly all the places licensed, and this meant a visit nearly once a quarter. Visits were nearly always unannounced. The chief inspector received 1200 reports a year from his subinspectors and submitted an annual report to the Secretary of State, which was presented to Parliament. The chief inspector had assured Lord Selkirk that he was fully satisfied that he knew what was going on in every place on his register.

It was true, Lord Selkirk continued, that there had been no prosecutions under the Act, but that was not a wholly satisfactory way of judging the success of the Statute because, besides noting the irregularities each year in the annual report, certificates and licences had been refused, and warnings had been issued. He agreed that the production of sera was not covered by the 1876 Act, but this work was covered by the Protection of Animals Act, 1911. Inspectors were appointed under the Therapeutic Substances Act, 1925, to ensure that the places where the work was carried on were suitable and that the animals were maintained in a healthy condition. If any sera were tested the process came under the 1876 Act. In 1948 the then Home Secretary had received a delegation who presented a number of specific cases. All these had been carefully investigated, and Mr. Ede came to the conclusion that no sufficient grounds existed, either in respect of the law or of its administration, to justify the appointment of a Royal Commission; and nothing had arisen recently to cause the present Home Secretary to take a different view.

QUESTION TIME

N.H.S. Charges

In answer to a question Mr. IAIN MACLEOD gave the following particulars, comparing the demand for drugs, dental treatment, and appliances under the National Health Service during the four months June to September, 1952, following the introduction of charges on June 1, 1952, under the National Health Service Amending Act, 1952, with the demand in the corresponding period of 1951 (see table).

Replying to a further question Mr. Macleod said the charges had led to some fall in the demand for drugs and to other savings in costs, but it was too early as yet to make an estimate of the financial saving likely to be effected.

B.C.G. Vaccine

Mr. P. F. REMNANT asked the Minister whether B.C.G. vaccine was now being manufactured in this country.—Mr. MACLEOD replied: Manufacture in this country will be considered as soon as the level of requirements justifies this course. Mr. REMNANT: Is the Minister aware that a considerable amount is being imported by air and that at present its manufacture here is illegal under the Therapeutic Substances Act? Will he at least give permission, by law if necessary, for it to be manufactured here?—Mr. MACLEOD: We import from Copenhagen and Paris but the amount involved at present totals only £1600 a year, and until the use of B.C.G. becomes more widely approved I do not think that there is any point in changing the present position.

Food-poisoning

Mr. J. K. VAUGHAN-MORGAN asked the Minister what steps he was taking, particularly in conjunction with the Minister of Food, to offset the continued increase in outbreaks of [illegible] LEOD replied: A major factor in [illegible] the recognition by both industry an [illegible] re and cleanliness in all aspects of food-handling, and much publicity work has already been done on this by the departments concerned, local authorities, and other bodies. At the same time, in conjunction with my department the Ministry of Food is considering what further measures can usefully be taken in the light of recent reports as regards meat and meat products, and is also looking into the subject of synthetic cream. I have also under consideration a revision of the Public Health (Infectious Diseases) Regulations so as to give wider powers in relation to food-poisoning.

Mr. VAUGHAN-MORGAN: Is the Minister aware that according to his Ministry's report 83 of the 539 outbreaks last year were in hospitals and institutions? Will he take whatever disciplinary action is necessary to stop this?—Mr. MACLEOD: Certainly.

Experiments on Living Animals

In answer to a question Sir DAVID MAXWELL FYFE stated that the total number of experiments performed in 1951 on living animals under the Cruelty to Animals Act, 1876, was 1,919,424. Of these, 1,665,120 experiments not involving any procedure more severe than simple inoculation or superficial venesection were performed without anæsthetics. Cats, dogs, horses, asses, or mules were used in 10,262 experiments.

	1951				1952

Elastic hosiery ordered through hospital service	2954	2901	2736	2951	2450	2354	5107	

---

*Includes elastic hosiery prescribed by general practitioners. There are no separate statistics for prescriptions issued by hospital outpatient departments.

†The courses for limited treatment usually cost under £1 and, since patients would have to pay the whole cost under the National Health Service, many may be assumed to have had the treatment privately.

Obituary

PHILIP HENRY MITCHINER

., C.B.E., M.D., M.S. Lond., D.Ch. Durh., F.R.C.S.

men have had more influence on the surgery of
than Philip Mitchiner, and he had won an almost
ry reputation as a clinical teacher. Though it
own that he had latterly been obliged to restrict
berant activities, the news of his death on Oct. 15
s a shock.

[Elliott & Fry

on June 17, 1888, he was the eldest son of
M. Mitchiner, and was educated at Reigate
ar School. At St. Thomas's Hospital, which he
in 1906, he was awarded many prizes and distinctions, including the Mead and Bristowe medals and Beaney scholarship. As a student he was one of the original members of the the combined Guy's and Thomas's contingent on the foundation of the medical unit of London University O.T.C., and this remained one of his outstanding interests. When he qualified in 1912, he obtained the gold medal in the M.B. examination, and his house-appointments at St. Thomas's included that of house-surgeon to Sir George Makins. In 1913 he obtained the F.R.C.S. and the following year the M.S. degree.

the outbreak of the 1914–18 war Mitchiner was
in and adjutant of the medical unit of London
rsity O.T.C., and he was retained in this appoint-
because of his administrative ability and against
ishes. At the beginning of 1915 he was appointed
al registrar at St. Thomas's, but in 1916 he managed
entangle himself and he proceeded on active service
Balkan front, where he was employed as a surgical
alist, first to a Serbian hospital and later, in 1917,
e 49th General Hospital. For his services he was
ated with the Serbian Gold Medal, the Order of
ava, and the Russian Order of St. Stanislas. Return-
o St. Thomas's in 1919, he served for a time as
ent assistant surgeon, but he gave up this appoint-
to join the Serbian Relief Fund. In 1920 and 1921
gain worked as a surgical specialist in Serbia, where,
g to war and typhus the normal medical services
almost entirely broken down. His work was of
imable value because of his knowledge of the
age and high surgical standing. On his return to
and he was appointed to the surgical staff of the
l Northern Hospital, and also completed his tenure
esident assistant surgeon at St. Thomas's, where
ecame assistant surgeon in 1922. His interest in the
C. continued, and he succeeded Colonel A. M. H. Gray
ommanding officer of the medical unit.

etween the two wars Mitchiner was intensely busy
teacher, consulting surgeon, examiner, and author.
Science and Practice of Surgery, written with Mr.
anis and first published in 1926, is possibly his
-known work. For many years he was an examiner
ondon University, and in 1936 he was appointed to
court of examiners of the College of Surgeons. In
Hunterian lecture to the college in 1933, he dealt
the problem of burns. In 1932, as a senior Territorial
er, he was appointed honorary surgeon to the King,
two years later he became full surgeon at St.
mas's. He was appointed C.B.E. in 1938. As a member
he senate he was also active in the affairs of the
versity.

t the outbreak of war in 1939 Mitchiner was first
loyed in the Northern Command and later as D.D.M.S.
the Anti-Aircraft Command of the whole country.
he latter part of the war he proceeded as consulting
geon to the Middle East. At the end of hostilities
was appointed C.B., and he held the rank of major-
eral in the Territorial Army.

During the war St. Thomas's had suffered considerably, and the dispersion of the hospital activities and buildings increased the work of the honorary staff. Mitchiner's administrative experience on his return to civilian life was of notable value to the hospital at this time, particularly in view of the coming of the National Health Service. Paradoxically he had to retire in March, 1948, because the retiring age at St. Thomas's had always been 60: within three months, the retiring age was advanced to 65, to conform with the general practice of the health service. He remained, however, an extremely busy man though he was no longer a member of the active surgical staff. He was chairman of the court of examiners of the Royal College of Surgeons from 1946 to 1948, having become a member of the council in 1943, and he only completed his term of office as vice-president shortly before his death. As member of the South West Metropolitan Regional Hospital Board, he served on a number of committees, and he was also a deputy-lieutenant of the County of London and deputy vice-chancellor of the University of London. He had a prominent part in shaping the destinies of the Association of Surgeons of Great Britain and Ireland over the past twenty years, and he was president at its last meeting in London.

His characteristics as surgeon, soldier, and teacher are reflected in tributes from friends. R. H. O. B., to whom we are indebted for biographical details, adds the following personal words:

"Mitchiner will always be remembered as a man who did many kind acts for many people and without any ulterior motive. He was a great champion of the under-dog against the powers of vested authority. An iconoclast, he had at the same time great constructive ability in administration. As an undergraduate teacher of surgery he was magnificent. A profound knowledge of facts and a droll and sometimes Rabelaisian power of expression impressed his students, and by amusing them he imprinted knowledge in their minds. As a surgeon he was original in many of his ideas and he was a rapid operator. As an examiner he was extremely shrewd and scrupulously fair, not suffering fools gladly although sometimes leaving them under the impression that they had done better than was in fact the case. As a member of any committee he could be counted on to have a firm grip of the facts under discussion, and to instil common sense into its deliberations. His work for the O.T.C. and Territorial Army was unique, and it is doubtful whether any non-professional soldier will ever equal him. For his friends the world will be a sadder place without him and many will miss being able to turn to him for helpful advice."

R. J. V. P. knew Mitchiner as his student, as his junior in the O.T.C., as a fellow officer in the Middle East, and finally as a fellow member of committees. He writes:

"Philip Mitchiner had a zest for life, a sincere sense of duty which lasted the course, an infallible gift for recognising the arrogant, the pompous, and the bully, and the most devastating wit in exposing these qualities. It was the last of these gifts which made him a legend, and which will lead, as with Abernethy, to every pointed medical story of his time claiming his fatherhood. There is one infallible test of authentic record. If in a tale his rapier pierced field-marshal, general, consulting physician, or matron, the record has the ring of truth. But never in his life did Mitchiner score a point over a student, a house-officer, or a private soldier.

"These tales will carry Mitchiner's name to posterity as one who abhorred insincerity, unfairness, and oppression. But in many hundreds of Thomas's men's memories there lives the kindly quaint figure with shorn head and thin-rimmed glasses, to whom they went with their scrapes, and their worries, and from whom they sought advice when starting on their career. As a teacher he scorned to sit on the fence or to qualify; he was dogmatic and emphatic, and none ever forgot what Mitchiner taught, though men sometimes met examiners whom he had not.

"Of my own memories of him two stand out; of a kindly, busy, amateur archæologist, exploring Palestine and Syria with a camera in one hand and a Bible in the other, and my final meeting when, a sick man, he spoke with all his old zest of the soldiers in Korea and their right to the best doctors.

"The Army, or perhaps, the uniform, was Mitchiner's enduring delight. No-one had less use for discipline, and he trod on more corns than anyone I have ever met; but he loved the little glories of military life, the bright ribbons, the hint of adventure that went with the uniform. He did more than most to reconcile the amateur R.A.M.C. officer to the inevitable constraint of Army life; they laughed with him at the insincerities, the stuffed pigeons, the façades. But they were often pulled up short by the simple phrases of a just and serious man, whose sense of duty crowned him with a dignity he feigned to despise."

His last house-surgeon before his retirement describes Mitchiner's impact on a younger generation:

"I took up my appointment as house-surgeon to Mr. Mitchiner with mixed feelings, for a wealth of anecdote had created a formidable figure. The container certainly looked harmless enough, but I was apprehensive of igniting the gunpowder said to be within. A characteristic response to my attempt to use a 'no touch' technique when doing a 'cut down' for transfusion soon reminded me that the Mitchiner legend was built round his detestation of pretentiousness. This quality could also be embarrassing, and my ears still burn at the memory of being told I looked hungry during a formal dinner at the Royal College of Surgeons, and at having to accept Mitchiner's own helping passed under the noses of the eminent, and the disapproving frowns of the liveried waiters.

"He was a loyal and considerate chief. Wrong-doing was corrected by a gentle 'Naughty boy, you shouldn't have done that'—though a repetition of the misdeed might well elicit something more in accordance with the legend. Most of the fireworks were reserved for the graphic illustration of his teaching, and as a teacher of undergraduates he had few equals in the expression of fundamental principles in a fundamental way. He had a wonderful way with patients, and the change in attitude of a difficult patient after his ward rounds was dramatic.

"I am one of many who have reason to remember his unobtrusive kindness. Those of us who worked under him in the immediate post-war years will remember Mitch with affection."

C. M. P. recalls his work for the students at St. Thomas's.

"Philip Mitchiner established a reputation as a witty and effective teacher of undergraduates and he was always a popular supporter of many student activities. By bent and education he was essentially a general surgeon and in that capacity he extended his interests considerably outside the purely professional arena. His services to the senate of London University and his devotion to the Territorial medical unit of that organisation are examples of that tendency. He possessed a clear head and a critical ability which made him a useful member of any committee, albeit his approach was at times brusque and lacking in the traditional courtesies. But his obvious sincerity and sound common sense robbed this attitude of any offence. His capacity for direct speech and clear judgment will be especially missed at the meetings of the council of the College of Surgeons.

"Mitchiner had character and also that element of it which inspires a strong sense of public duty. This possession, I think, enabled him to carry on much valuable work in council and committee despite the recurrent illnesses which harassed him in his latter years."

A. L. C. writes with nostalgic pride as one who received his "military baptism by serving in Mitchiner's Army."

"The R.A.M.C., and particularly that part of it associated with the Territorial Army, has suffered an irreparable loss in the death of Philip Mitchiner. No more shall we see that slightly bizarre but ever popular figure with close-cropped head, kindly eyes, and impetuous tongue. There was a touch of Grimaldi about him that endeared him to his juniors. His devotion to the Territorial Army never flagged. Long years of service included many important appointments. The two in which, perhaps, he wielded most influence were those of commanding officer of the medical branch of the University of London O.T.C. and of D.D.M.S. of Anti-Aircraft Command. In the former there passed through his hands many generations of students who were to win honour and distinction in the recent war, and in the latter he created the medical services of General Pile's famous command. No-one contributed more towards the welding together of the Regular and Territorial elements of the Corps into their present close and happy relationship. Kindly and generous-hearted, he was quick to pounce on inefficiency and pomposity, exploding them with a robust phraseology, a little suggestive perhaps of the 'rude and licentious soldiery' whom he loved so well."

W. H. O. leaves St. Thomas's men to recount the Mitchineriania, true and apocryphal, but "as a contemporary, a comrade in uniform in three wars, a friend and admirer of many years' standing, a fellow member of the Surgical Travellers and the council of the College of Surgeons, I should wish to pay my tribute to a very great man."

"Mitchiner's courage, honesty, and loyalty," he writes, "are the qualities that come at once to mind. He had courage—physical and moral—above most men. If he believed in a cause he would fight for it, if he believed in a man he would support him. There was no fencing with Philip. He came to the point at once, and further he left no possible doubt as to what the point was. His language was direct, forcible, almost Chaucerian in its imagery, but phrases that, coming from others might have given offence, were detoxicated by his glowing sincerity. Soft soap and compromise were alien to his nature. He was a remarkably efficient committee man, better able than most to see the essential point of a problem, more ready than most to state it clearly and forcibly. He had, in debate, the natural eloquence of a man of action.

"His personal appearance went well with his colourful and forceful character. He had the clear-cut features and piercing eyes of a medieval pope. He wore his hair clipped short. He dressed simply and travelled about London, bareheaded and on foot. In his general appearance, his erect stance, and his direct look, he recalled the portrait of Anthony Carlisle by Shee, the most striking painting in the council room of the College of Surgeons. Most of his friends will think of him in uniform, for Mitchiner spent many years on active service. He was decorated more than any civilian, and in full dress uniform on ceremonial parades, his soldierly bearing and bemedalled chest picked him out at once for attention. Off duty in a theatre of war, his disregard of display and even of the prescribed details of Service dress were sometimes an embarrassment to his fellows and his superior officers.

"A very great surgeon, and a loved member of our profession, has gone. He was unselfish, he was loyal, he was an indefatigable worker. Of few men could it be said with equal sincerity that British surgery will never be the same without him."

Mitchiner married in 1928 Miss Margaret Philpott, who survives him.

WILLIAM EWART GYE

M.D. Edin., F.R.C.P., F.R.S.

W. E. Gye, who died in Australia on Oct. 13, was an outstanding figure in British cancer research. He was the son of a railway signalman, Charles Bullock, being born on Aug. 11, 1884. In his early days he worked as a "knocker-up" and had experience on the railways and in a factory. But his mind was on higher things, and a fortunate set of circumstances enabled him to continue his education and, with the aid of a scholarship, to graduate as M.D. at Edinburgh (with gold medal) in 1913. On his marriage he changed his name to Gye, his wife's maiden name. After a short period in general practice, he turned to cancer research, obtaining a position on the staff of the Imperial Cancer Research Fund under Bashford and, later, Murray. He became familiar with the fundamental work on mouse tumours in progress there, and published a number of papers on pathology, including some on the fringes of biochemistry.

He served during the 1914–18 war in France and Italy as a captain in the R.A.M.C. As a result of his war experiences he became interested in anaerobic infections of wounds and "defence rupture" through the agency of chemical substances, particularly calcium salts. Five papers were published with W. Cramer on this subject, the first bearing the title On a New Factor in the Mechanism of Bacterial Infection. One of the substances causing "defence rupture" was colloidal silica, and it was not surprising that he turned next to silicosis, collaborating with E. H. Kettle. It is believed that he had encountered the industrial hazards of silicosis in his very early days.

After the 1914–18 war the programme of the National Institute for Medical Research, then in its beginnings, included an attack on virus infections. Gye joined the staff in order to study dog distemper. While waiting for tock of virus-free dogs to be bred, he gained experience viruses by working with that of Rous's fowl-sarcoma, ving been intrigued with this remarkable agent since earlier cancer research days. When the dogs were ally ready, Gye was so deeply engaged in the problem fowl tumours that H. H. Dale, the director, allowed m to carry on with it; and Laidlaw joined the staff r the distemper work.

In 1925 a considerable sensation was caused by Gye's per, published in THE LANCET, with J. E. Barnard, the Ætiology of Malignant New Growths. It was aimed that fowl tumours, and cancers in general, ere due to viruses which were cultivable in a cell-free edium and could be portrayed by ultraviolet photoaphy. The specificity of various growths was deterined not by the properties of this virus but by a specific factor" derived from the host. This was an genious attempt to reconcile the idea of a ubiquitous tential cancer virus with the extreme individuality cancers as met with in Nature, and the thesis was eveloped in following years, especially in a book with W. Purdy, *The Cause of Cancer*. Unfortunately, her workers were not able to reproduce the fundaental experiments on which Gye's thesis rested. One portant fact, however, was established—that the ous virus was inactivated in the presence of complement by anti-fowl sera. Subsequent work with Purdy tumours which grew both in fowls and in ducks further tended knowledge of this matter.

In 1936 Gye succeeded Murray as director of the mperial Cancer Research Fund and he played the leading art in planning its laboratories now existing at Mill ill. In 1949 he reported the propagation of mouse mours by means of dried tissue and drew the conclusion hat a virus must be their cause, even though filtration ad not been achieved. It appears, however, that this as a premature conclusion, for James Craigie later emonstrated that a particular kind of cell, present many cancers, was unexpectedly resistant to freezing, rying, and other insults. The presence of such cells ccounted for the positive results with dried tumours.

Gye's contribution to cancer research is much more mportant than the above account would suggest. he filtrable fowl tumours described by Rous in 1911 ad, in the '20s, been forgotten, or were ignored or dismissed as something sui generis with no bearing on the ancer problem. Peyton Rous had lost heart at the lack f recognition of their significance. Gye brought them o life again, compelled their acceptance as true tumours, nd made the virus theory of cancer once more a living ssue. It is true that his two claims to have proved this hesis have failed to carry conviction. Nevertheless, t is largely due to Gye that the virus theory is today one heory of cancer ætiology which has to be reckoned with. He had a masterly lucidity in expounding his ideas oth in writing, in lectures, and in talking to visitors.

Gye was a man of much charm and many interests. Through an interest in politics he had many friends n public life, and he was also a keen cricketer. Unfortunately he never fully recovered from the effects f a renal infection contracted while he was still a fairly oung man, and in the last few years of his life his health was poor.

He was elected F.R.S. in 1938. In 1943 he was appointed professor of experimental pathology at the Royal College of Surgeons, and on his retirement in 1949, he became emeritus professor. His first wife, by whom he had three sons, died in 1943, and he later married Dr. Ida Mann, professor of ophthalmology at Oxford. On medical advice he retired in 1949 to the more equable climate of Western Australia.

HUGH TUKE ASHBY

B.A., M.D. Camb., F.R.C.P.

Dr. Ashby carried a name which for two generations has meant much to the Royal Manchester Children's Hospital, where he and his father had together served for a span of over seventy years.

He was born in 1880, the son of Henry Ashby, F.R.C.P., and he was educated at Clifton College and the Universities of Cambridge and Manchester. After qualifying in 1907 he held resident appointments at Manchester Royal Infirmary and at Manchester Children's Hospital, then known as Pendlebury Hospital. After postgraduate visits to pædiatric centres at Marburg, New York, Boston, and Philadelphia he returned to Manchester where he became senior medical officer to the outpatient department of the Children's Hospital, and in 1912 he was elected to the staff as assistant visiting physician. About this time he was also appointed to the staff of the Salford Royal Hospital, and later he joined the staff at Booth Hall Infirmary for Children and became visiting physician for children to the Manchester public-health committee. He also lectured on diseases of children at the university.

His experience in the crowded outpatient clinics and wards of the Manchester hospitals in the early years of the century soon drew his attention to the urgent problem of infant mortality, and his book *Infant Mortality*, published in 1915 and revised in 1922, emphasised the difficulties that mothers had to contend with in those days, and paved the way for the improvement of midwifery and the provision of antenatal and infant-welfare services and of cleaner milk. In 1922, with the help of the late Charles Roberts, he completed the not inconsiderable labour of revising his father's textbook written with G. A. Wright, on the *Medical and Surgical Diseases of Children*.

His own papers were largely concerned with the dietetic disorders of infancy, and the anæmias and secondary results of malnutrition, that were so common at that time. "Ashby's writings," T. N. F. recalls, "always emphasised the practical aspects of this subject, an attitude of mind that was an essential feature of his approach to clinical medicine.

"He had pre-eminently that love for, and understanding of, children and wide experience of their demeanour in health and disease that are a first requisite in the good children's physician, and which gave him an almost uncanny insight into the problems of diagnosis and prognosis. Not uncommonly in his outpatient notes would appear some such unorthodox diagnosis as 'mal de la mère,' written in a hand that might need some experience of his writing to elucidate, that went straight to the heart of a difficult clinical problem.

"On a ward round, after examining a sick child and prescribing or approving the treatment, he would lean over the end of the cot. There would be a pause, while he and the distressed acutely ill child seemingly gazed thoughtfully at each other, as though some mystic communion passed between them; and then with a laconic 'He'll do,' Ashby would pass to the next child, and his worried house-physician would feel assured that all would be well. Or (at a discreet distance from the older more comprehending child), 'It's a bad do there,' and the outlook was correspondingly gloomy. He was indeed a master of the homely phrase that immediately put nervous and worried parents at ease; and he would, as effectively, bring a committee meeting that was not getting anywhere down to the point at issue, or, most disarmingly, prick the bubble of unnecessary verbosity or pomposity."

Ashby was one of the founder members of the British Pædiatric Association and his colleagues elected him their president in 1949. Later he exchanged this well-deserved national honour for the presidency of the Manchester Pædiatric Club. He was also a vice-president of the Medical Defence Union. After his retirement from the staff he continued to take a close interest in the affairs of the Manchester Children's Hospital and particularly in the health and welfare of the nurses, who owe more than many realise to his constant efforts on their behalf. He died on Oct. 9 at his home at Didsbury.

Of Ashby's life outside the ward and the consulting-room his friend T. M. B. writes:

"Hugh was a stoic. All his life he suffered a progressive crippling disablement to which he never referred. In spite of this he determined to, and did, enjoy a full round of sports. Fond of tennis, he confined himself to clever placing of the ball to dismay his opponents. As a golfer, his short game, on his day, was masterly. For 25 years, he was a co-secretary to the Manchester and District Medical Golfers' Association, serving a year as captain, and finally being elected an honorary life-member. From his youth he was accustomed to sailing on the Norfolk Broads, and he was always skipper of the yacht on which he, the late Daniel Dougal, the late Lawrence Kilroe, and I enjoyed many happy weeks before and after the first world war.

"He was a man of simple tastes, with a dislike of any ostentation. Essentially kind and considerate, the trite saying 'He never had an enemy' indeed applied to him. But he was tenacious in holding positive opinions regarding right or wrong, and expressing them forcibly. At home he was a keen amateur gardener, raising an abundance of flowers, especially roses, and he loved to potter in his greenhouse.

"His strong, clear voice, his blue eyes, his laugh with its curious chuckle, and above all his kindly ways will remain a lasting memory for his friends."

Dr. Ashby leaves his widow with a son and two daughters.

Appointments

Richards, Myrtle, M.B. Edin., D.C.H.: asst. M.O., Warwickshire.
Rigby, W. E., M.B. Manc., C.P.H.: asst. county M.O., Warwickshire.

The Hospital for Sick Children, Great Ormond Street, London:

Forsyth, Constance, M.D. Edin., M.R.C.P.: asst. medical registrar.
Halfhide, A. W., M.R.C.S., D.L.O.: senior E.N.T. registrar.
Holt, K. S., M.D. Rochester, N.Y., M.R.C.P.: house-physician.
Horton, Jean, M.B. Lond.: junior resident anæsthetist.
Hugh-Jones, Kenneth, M.D. Lond., M.R.C.P.: asst. medical registrar.
McGreal, D. A., M.B. St. And., M.R.C.P., D.C.H.: house-physician.
Rooms, Margaret, M.B. Lond.: junior resident anæsthetist.
Smyth, B. T., M.B. Belf., F.R.C.S.: house-surgeon.
Stephens, D. J., M.B. Leeds: house-surgeon, orthopædic and plastic department.
Wilson, J. A. C., M.B. Edin., M.R.C.P.: house-physician.

Liverpool Regional Hospital Board:

Gifford, J. H., M.B. Manc.: tuberculosis M.O., North Liverpool area.
Mosscrop, L. E., L.R.C.P.E., D.A.: part-time consultant anæsthetist, Southport and Ormskirk groups.
O'Beirn, Nicholas, M.B. N.U.I.: medical director and asst. chest physician, no. 2 mass-radiography unit.
O'Malley, A. G., M.B. Edin., M.CH.ORTH. Lpool, F.R.C.S.E.: part-time consultant radiologist, hospitals in the Warrington area.
Shatwell, G. L., M.CH.ORTH. Lpool, F.R.C.S.: part-time consultant orthopædic surgeon, hospitals in the St. Helens area.
Snell, Emanuel, L.R.C.P.E., D.P.H.: tuberculosis M.O., East Liverpool area.
Weldon, H. J., M.B. N.U.I., D.A.: part-time consultant anæsthetist, Southport and Ormskirk groups.
Whitehead, A. S., M.D. Lpool, M.RAD., D.M.R.D.: part-time consultant radiologist, Mill Road, Newsham General, and Bootle Hospitals.
Wri Lpool, D.M.R.D.: part-time consultant in the St. Helens and Warrington groups.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Births, Marriages, and Deaths

BIRTHS

Brown.—On Oct. 1, at Colac, Victoria, Australia, to Joan (née Frecheville), wife of Dr. A. Graham Brown—a daughter.

Dick.—On Oct. 4, to Gurna (née Isles), wife of Dr. T. H. Graham Dick, 39, Malone Park, Belfast—a daughter.

Fisher.—On Oct. 12, at 125, Castle Lane, Bournemouth, to Rosemary (née Sterling-Hill), wife of Dr. James Fisher—a daughter.

Fryer.—On Oct. 10, at Farnborough, Hants, to June (née Bradley), wife of Flying-Officer D. I. Fryer, M.B.—a son (Timothy Peter).

Groundes-Peace.—On Oct. 18, to Zara (née Yeoman), wife of Dr. John Groundes-Peace, M.B.E., of 6, Belford Mews, Edinburgh—a son.

Happel.—On Oct. 12, to Margaret, wife of Dr. John Happel, of Ropley, Hants—a daughter.

Towers.—On Oct. 14, to Beryl Margaret Helen (née Davies), wife of Dr. Bernard Towers, of 74, Colchester Avenue, Cardiff—a daughter.

MARRIAGES

Wilson—Smith.—On Oct. 11, Edric Frank Wilson, F.R.C.S., of Plymouth, to Dorothy Smith, of Chipping Campden.

DEATHS

Andrew.—On Oct. 14, at 15, Howell Road, Exeter, Henry Andrew, M.R.C.S., aged 86.

Carew Hunt.—On Oct. 17, at The Barn House, Church Handborough, Oxon, Mary Helen Carew Hunt, M.D. Brussels.

Hay.—On Oct. 17, at 555, Lincoln Road, Peterborough, William Peach Hay, M.B. Edin., aged 82.

Mitchiner.—On Oct. 15, Philip Henry Mitchiner, C.B., C.B.E., M.D., M.S. Lond., F.R.C.S., of 6, Morpeth Mansions, London, S.W.1, aged 64.

Morris.—On Oct. 14, at 27, Okehampton Close, London, N.12, John Mudie Morris, M.A., M.B. Edin., D.P.H., formerly of Neath, Glamorgan, aged 86.

Perram.—On Oct. 16, at Overstowey, Teignmouth, Devon, Edward Arthur Perram, M.D. Lond., aged 88.

Notes and News

GENERAL PRACTICE IN NORTHERN IRELAND

In its report[1] for the year 1951–52, the Northern Ireland General Health Services Board observes that during the year the proportion of the population included in doctors' lists increased slightly from 98·43 to 98·94%. The average number of patients on a doctor's list increased by 43 from 1864 to 1907. This was due to a fall in the number of doctors (including assistants) on the list from 772 to 744—a decrease occasioned by the operation of the Health Services (Temporary Provisions) Act (Northern Ireland), under which the board limited additions to the list to 4, although 32 doctors died, retired, or resigned. The board remarks that its attempts to encourage the public to exercise discretion in its calls on the medical services had met with a substantial response. "There remained, however, a considerable body of persons who, despite numerous public statements to the contrary, continued to hold the erroneous view that the Health Services are paid for wholly from their insurance contributions and that they must, therefore, try to obtain full value regardless of the increased burden in the form of taxation which must arise from their heavy demands for medicines and appliances."

INTEGRATION OF CHILD HEALTH SERVICES

One of the most important lessons from the first four years of the National Health Service has been the need for better integration of its three branches and for some redistribution of responsibilities between them. This lesson is nowhere more evident than in the child health services, where all three branches play an important part. Thus at a conference held at Whittington Hospital, London, on Oct. 11, Dr. L. J. Stoll argued that the general practitioner should resume his rightful position at the centre of the medical services. The general practitioner alone, said Dr. Stoll, was chosen by the patient, was always at hand, and saw the patient throughout his life. If the family doctor were to undertake the periodic examination of infants and children which were now made by the assistant medical officer of health, he would have a complete record of physical development and illness. The health visitor should be in much closer contact with the family doctor, whose knowledge of the family and its background would be invaluable to her in her work. Furthermore, to hasten the turnover of inpatients, staff nurses from the local hospital should do six months "on the district," nursing the children at home under the supervision of the family doctor and the consultant from the local hospital.

Dr. Catherine Mackie also urged the need for closer understanding between the various parts of the child health services; but she suggested that this might be achieved by giving experienced assistant medical officers greater responsibility in a limited area of their borough, where they would guide the team of medical officers, health visitors, and clinic nurses, know the schools and their teachers, and discuss common problems with doctors practising in the neighbourhood. She added, however, that ideally preventive and curative medicine should not remain separated; eventually both should be practised by the family doctor working from a health centre.

As a social worker, Miss I. M. Neil was disconcerted by the tendency to transfer sessions from local clinics to hospitals. Though administratively convenient, this lost to the patient the personal atmosphere of the local clinic; wherever possible, the specialist should be brought to the child, and not the child to the specialist. Coöperation with general practitioners might be improved by their getting to know and to use the resources at the command of the local authority.

Dr. S. Yudkin deplored the almost total absence of integration between the hospital on the one hand and general practitioners and the local health authority on the other. The result of this was long lists of chronic outpatients and lack of information among family doctors about their patients. At the Whittington Hospital patients were always referred back to their doctor; and letters were sent to the doctor on the day of discharge. Dr. Yudkin agreed that in the future the care of the child should be mainly the task of the general practitioner; but the hospitals must help by keeping him informed of recent developments.

---

[1] Northern Ireland General Health Services Board: Fourth Annual Report, 1951–52. Pp. 47. 1s.

Other speakers also expressed uneasiness about the division responsibilities. Dr. Lindsey Batten, for example, marked that the local authorities and hospitals could, by xpanding their services, eliminate the general practitioner; ut he himself was convinced that the family doctor's authority ust be restored. Dr. E. Hinden admitted that the hospital nd local authority were doing more and more work; but e suggested that this was the outcome of reluctance of amily doctors to participate in an integrated scheme. Dr. . M. Clayden evidently felt no such reluctance; for he alled on medical officers of health to convene regular meetings t which practitioners could exchange information with ther workers in the child health services. Dr. D. G. Berry, owever, held that health centres and increased participation y the family doctor in the work of hospitals were essential reliminaries to integration of the services.

Summing up, Prof. A. A. Moncrieff, the chairman, eminded the meeting that the present period is one of transiion and experiment. Clearly the status of the family doctor nust be restored; and the health visitor and family doctor hould work together. Clearly, too, it would be better if ospitals were local centres with local connections. The public hould be better informed of the services provided for the are and welfare of children.

DISTRICT NURSING IN LONDON

The London County Council pays for 90% of the cost of unning the home nursing service in London: but the emaining 10% (which this year is likely to amount to some 30,000) has to be found by the voluntary committees. Many nembers of the public mistakenly believe that the whole cost s borne by the authorities; and the Central Council for District Nursing in London has appealed to practitioners to correct his impression. Sir Harold Kenyon, the chairman, remarks hat "many who use the service would be only too pleased o make a donation if they were aware of the facts." It would, he adds, be most unfortunate if the home nursing service, the demands on which are constantly increasing, were to lose its voluntary status through lack of necessary funds. Donations may be sent to the central council, 25, Cockspur Street, London, S.W.1.

ANIMAL WELFARE

A well-developed conscience is always a better custodian of good behaviour than the law and its penalties. In this country conscientious concern for the welfare of laboratory animals is now so general that most laboratory workers do more to ensure it than the law requires of them. Hence it is not always easy, as the Universities Federation for Animal Welfare[1] (UFAW) knows, to offer guidance to members of other countries who wish to forward legal protection for laboratory animals. During the past year such a request came from scientists in Israel, and UFAW had to explain that our Cruelty to Animals Act, 1878, is too complicated to be readily understood abroad, and that its value depends largely on the way it is administered. The scientific subcommittee of the federation, however, with the help of other British scientists, is preparing draft suggestions to submit to Israel, in which the British law is made as clear as possible, and those points which deserve to be included in any new legislation overseas are emphasised. Interest in the subject is certainly growing, as sales of the federation's handbook on *The Care and Management of Laboratory Animals* indicate: copies have now gone to all parts of the world.

Our own standards, of course, are still capable of improvement. The annual report mentions two changes made for humanitarian reasons last year at the Lister Institute. Sheep used to produce vaccine lymph are now given pentobarbitone before scarification; and before the lymph is collected they are killed with a captive-bolt humane-killer. UFAW points out that no Order has yet been made to control the preparation of veterinary therapeutic substances, such as would bring inspection into line with the inspection carried out by the Ministry of Health, under the Therapeutic Substances Act, 1925, in the case of therapeutic substances for human use. Such an Order could be made by the Minister of Agriculture, under the Diseases of Animals Act, 1935; and indeed it was promised by the Chief Veterinary Officer of the Ministry of Agriculture in January, 1949, to a deputation which included UFAW representatives. It is surely time this promise was kept.

University of Cambridge

On Oct. 11 the following degrees were conferred:

M.B., B.Chir.—P. G. Allen, *M. A. Baddoo, R. J. H. Harris, *L. B. P. Hartley, J. H. Kerr, *D. N. H. Owen, *J. D. H. Slater.

* By proxy.

University of London

At a recent examination the following were successful:

Academic diploma in [illegible] Akram, J. A. Campbell, Jean E. [illegible] an, C. E. Marshall, G. A. K. Misse [illegible] Watson, K. H. White, Mary I. Wright, Saiyid Sibte Hasan Zaidi.

External diploma in clinical pathology.—Gyawni Aung, R. M. Cross, David Hewspear, James Ward.

At a recent examination for the academic postgraduate diploma in public health Valaydon Poonoosamy and William Dharmarajah Ratnavale were successful.

On Friday, Nov. 21, Prof. J. Gough is to give a lecture on Pneumoconiosis the World Over. On Monday, Dec. 8, Dr. P. Gyorgy, professor of nutrition in pædiatrics in the University of Pennsylvania, will deliver a lecture on Blood Group and Related Polysaccharides in Growth and in Resistance to Disease with special reference to Human Milk. Both lectures are to be given at the London School of Hygiene, Keppel Street, W.C.1.

University of Sheffield

Dr. S. Oleesky has been appointed lecturer in therapeutics, Dr. R. S. Weetch, temporary lecturer in therapeutics, Dr. D. Beasley, temporary lecturer in child health, and Dr. E. K. Blackburn, honorary lecturer in pathology.

Royal College of Physicians of London

Dr. Richard R. Bomford will deliver the Bradshaw lecture on Thursday, Nov. 6, at 5 P.M., at the college, Pall Mall East, S.W.1. He will speak on Changing Concepts of Health and Disease, with Particular Reference to "Psychosomatic Medicine."

British Medical Association

Sir James Learmonth will deliver the Victor Horsley lecture at B.M.A. House, Tavistock Square, London, W.C.1, on Thursday, Dec. 11, at 5 P.M. He will speak on Ischæmia in Surgery.

Royal Institute of Public Health and Hygiene

On Nov. 10, at 4.30 P.M., Major-General H. C. D. Rankin, M.B., will deliver the Blackham lecture at the institute, 28, Portland Place, London, W.1. His subject is to be a Review of Army Health.

Institute of Laryngology and Otology, London

On Saturday, Nov. 8, at 11.30 A.M., at the institute, 330, Gray's Inn Road, W.C.1, Dr. Arthur W. Proetz (St. Louis, Mo.) will deliver a lecture on Olfaction.

On Friday, Nov. 21, at 4.30 P.M., Mr. I. Simson Hall will deliver the annual address. He will speak on Conservative Treatment of Cancer of the Larynx.

Postgraduate Course in Rheumatism

The Empire Rheumatism Council is to hold a postgraduate course on Nov. 21 and 22, at the Arthur Stanley Institute, Peto Place, Marylebone Road, London, N.W.1. Prof. R. E. Tunbridge will give the opening lecture on Diagnosis of the Rheumatic Disorders at 4.30 P.M. on Friday, 21st. Further particulars may be had from the general secretary of the council, Tavistock House North, Tavistock Square, W.C.1.

Royal Society

At a meeting on Thursday, Nov. 6, at 4.30 P.M., at Burlington House, London, W.1, Mr. A. S. Parkes, F.R.S., and Dr. Audrey U. Smith will read a paper on Regeneration of Rat Ovarian Tissue Grafted after Exposure to Low Temperatures. On Thursday, Nov. 20, Prof. A. J. Kluyver, who holds the chair of microbiology at the University of Delft, will deliver the Leeuwenhoek lecture. He will speak on the Changing Appraisal of the Microbe.

Institute of Biology

The Biological Council, which is composed of representatives of some 15 biological societies, has resolved to become an advisory body to the institute. At a meeting of the council on Sept. 29, the following officers were elected: chairman, Mr. W. P. K. Findlay, D.SC.; hon. treasurer, Prof. F. L. Warren, D.SC.; hon. secretary, Mr. J. L. Cloudsley-Thompson, who may be addressed c/o the institute, Tavistock House South, Tavistock Square, London, W.C.2.

---

[1] Twenty-sixth Annual Report, 1951–52. Published by UFAW, 284, Regent's Park Road, Finchley, London, N.3. Pp. 28.

West Midlands Physicians Association

The general meeting of this association will be held at Dudley Road Hospital, Birmingham, on Saturday, Nov. 1, at 11 A.M.

Stephen Paget Lecture

Sir Howard Florey, F.R.S., will deliver the Stephen Paget lecture at a meeting of the Research Defence Society to be held at University College, Gower Street, London, W.C.1, on Thursday, Nov. 20, at 5.30 P.M. He will speak on the Advance of Chemotherapy by Animal Experiment.

National Insurance Advisory Committee

The Minister of National Insurance has appointed Dr. Benjamin Hutchison to be a member of this committee in succession to Dr. John Ritchie, who has resigned. Dr. Hutchison is vice-chairman of the executive council and chairman of the local medical committee in Lanarkshire.

School for Spastic Children

On Oct. 14 Lord Horder opened a school for spastic children at Swindon. The school has been sponsored by the Swindon and District Hospital Management Committee and the Wiltshire County Council and Swindon Borough Council education committees.

British Standards

The British Standards Institution has issued standards for rubber ice-bags for hospital use (B.S. 1898 : 1952), and for metal-framed wheeled screens for use in hospitals (B.S. 1895 : 1952). Copies (price 2*s.*) are obtainable from the sales branch of the institution, 24, Victoria Street, London, S.W.1.

The institution has also issued a draft standard for sedimentation tubes for red blood corpuscles (CO [LBC] 4936), comments on which should be submitted before Nov. 27.

Midland Tuberculosis Society

The following officers have been elected for the 1952-53 session : President, Dr. J. E. Geddes ; secretary, Dr. G. W. N. Luntz ; treasurer, Dr. H. J. T. Ross ; members of committee, Dr. P. G. Arblaster, Dr. A. Gordon Evans, Dr. T. W. Lloyd, and Mr. S. J. McHale.

Medical Honour

Captain Robert Barnes, M.B. Adelaide, R.A.A.M.C., has been appointed M.B.E. in recognition of gallant and distinguished services in Korea.

Kathleen Schlesinger Fellowship

The Medical Research Council invite applications for the fellowship which is tenable at the National Hospital for Diseases of the Nervous System, Queen Square, London, for one year in the first instance, renewable annually up to a maximum of three years in all. The annual stipend will be within the range £700–1000. Preference will be given to *candidates who elect to work on the mechanisms* underlying degenerative processes affecting the brain. Applications, including an outline of the proposed research and the names of two referees, should be sent to the secretary of the council, 38, Old Queen Street, S.W.1, not later than Nov. 15.

CORRIGENDUM : *Education by Travel.*—At the end of his article in our issue of Aug. 30 (p. 396) Dr. Raymond Whiteh mentioned the List of Whole-time Awards for Scientific Research, other than Professorships, offered by Public and Private Bodies in Great Britain and Northern Ireland. This list is issued, not by Messrs. Gale & Polden who printed it but by the Royal Commission for the Exhibition of 1851, 1, Lowther Gardens, London, S.W.7. Copies may be obtained from the Secretary at this address.

Diary of the Week

OCT. 26 TO NOV. 1

Monday, 27th

NSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Mr. J. T. Abrams, PH.D. : Deficiency Diseases of Young Animals.
INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel : lecture-demonstration.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Dr. H. F. Brewer, and Dr. A. E. Mourant : Perils of Blood-transfusion.
UNIVERSITY OF OXFORD
2.30 P.M. (Radcliffe Infirmary). Dr. Wesley Spink (Minnesota) : Intracellular Parasitism in Brucellosis.
MANCHESTER MEDICAL SOCIETY
9 P.M. (Medical School, University of Manchester.) *Section of General Practice.* Prof. R. Platt : Opportunities for Research in General Practice.

Tuesday, 28th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Mr. R. M. Haines : Tumours of the Uterus. (Erasmus Wilson demonstration.)
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Section of Surgery.* Dr. L. S. Fallis (Detroit) : Acute Pancreatitis.
8 P.M. *Section of Medicine.* Dr. C. Dukes, Dr. W. Trevor Cooke, Mr. E. C. B. Butler : Intestinal Granulomata and Reticuloses.
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. E. J. Moynahan : Collagen.
ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5 P.M. Mr. T. M. Tyrrell : Epiphora.
WEST END HOSPITAL FOR NERVOUS DISEASES, 40, Marylebone Lane, W.1
5.30 P.M. Mr. G. C. Knight : Subarachnoid Hæmorrhage.
PADDINGTON MEDICAL SOCIETY
8.45 P.M. (St. Mary's Hospital, W.2.) Dr. L. Zeitline : Genius and Madness. (Presidential address.)
MANCHESTER MEDICAL SOCIETY
4.30 P.M. Mr. D. Lloyd Griffiths : Fractures and Fracture-Surgeons. (University lecture.)

Wednesday, 29th

ROYAL SOCIETY OF MEDICINE
8.30 P.M. Mr. Bernard Darwin : Dickens's Doctors. (Lloyd Roberts lecture.)
INSTITUTE OF DERMATOLOGY
5.30 P.M. *Dr. R. W. Riddell : Tinea Infections.*
INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

THE INDIVIDUAL AND THE GROUP IN MODERN MEDICINE*

R. J. V. PULVERTAFT
O.B.E., M.D. Camb., F.R.C.P.
ROFESSOR OF CLINICAL PATHOLOGY IN THE UNIVERSITY OF
LONDON, AT WESTMINSTER MEDICAL SCHOOL

LEAVING on one side the technicalities of clinical athology, I propose to consider what influences are moulding our professional behaviour, and in what way we, as doctors, reflect the contemporary climate of hought. For no-one today can be a hermit; perhaps in no age has man been so assaulted by persuasion. Indeed, I might be excused were I to spend all the time at my disposal in deploring the wholly excessive amount of information and opinion that now inspissates the ether and reduces whole forests to wood-pulp and dismay. For the greater part of recorded time man has deplored disaster when it has occurred; it was left to this generation, in daily prodigality, to bewail in addition disaster to come.

But I shall resist the temptation and instead ask the question, "what is it that differentiates the age we live in from others before it?" The question answers itself; it is surely the search for an acceptable compromise between the individual—always essentially remote, unique, and rebellious—and the herd into which a contracting, overpopulated, and overelaborated world seeks to constrain him. This is, of course, the oldest problem of civilisation; but it has been posed in stark crudity today both by the division of the world into Russianism and Americanism, and by the often frenzied efforts of every country to contrive the maximum degree of order within its own confines while permitting, at least in some countries, the maximum degree of privacy and licence to the individual. The pendulum has swung far towards the development of impersonal and group values at the expense of private and individual ones; and both in medicine as a whole and in clinical pathology we are involved in this tendency. We can no more stand outside it as scientists than can the artist; just as the incoherent nausea of the '20s expressed itself in the fœtid poetry of those years, so we doctors of today sail, without even realising it, as the tempests of our time drive us.

It really is important, I think, for each of us to consider his attitude towards tendencies in our profession, and to express that attitude. The obligation to orientate or reorientate our activities is ours, and can be delegated to none.

In facing the world's troubles I note two popular evasions. The first is to find a simple paranoid explanation—such as that all evil is due to an international Jew-Banker conspiracy or an international antisemitic trust. The other is an equally fallacious confidence in the existence somewhere of a committee of first-class brains who, in spite of all appearances, are looking after things. I must admit that until quite recently I believed in that committee: until, in fact, advancing years forced committees upon me—when I found, to my horror, that committees, however egregious, were composed of puzzled asses like myself. Committees are necessary evils; but they are staffed largely by men too lazy, too old, or too inefficient to manage their own affairs, seeking in extenuation to manage those of others. Unlike an army, whose pace is that of the slowest man, a committee's intelligence is well *below* that of its stupidest member, who is often oneself. Occasional gleams of light flatter to deceive. I remember a committee man whose contributions were always startlingly different; but soon, alas, I realised that it was because he never, by any chance, was referring to the matter on the agenda.

Our world is not run by an international conspiracy or by a divinely wise committee: it is run by you and by me. And unless we pause now and again to see how we are running it, we may well find ourselves outrageously trimming our sails to inauspicious breezes.

SELECTION OF DOCTORS

In considering how far we have moved from private enterprise to impersonal patronage it is well to remember that a revolution has taken place in the method whereby our profession is recruited. In Eire today 95% of the medical students are supported by their parents or by themselves, and in my youth a similar condition obtained here. But in Great Britain at least 80% of medical students are supported by grants of some kind. I should be the last to deplore this, for I fancy that the tendency began after the 1914 war, when, with my contemporaries, I gratefully, if with some bewilderment, accepted my fellow citizens' benevolence. It is not surprising, however, that the opportunity of belonging without expense to the most lucrative profession outside the black market has attracted a flood of applications, far exceeding the vacancies in schools or the requirements of medicine. In one medical school male applicants for 30 vacancies numbered 540 last year; 120 women applied for 5 vacancies. (A great many, of course, applied to more than one school, and about 1 in 3 were eventually admitted somewhere.) This thirst to succour suffering humanity must make all but the cynic blush with pride; but even the most unsuspicious mind must wonder whether a method of medical recruitment which involves no personal sacrifice, still less hardship, for anyone attracts the right men and women. Moreover, it is well to remember that the dispensation of national patronage is vested in remarkably few hands. All these candidates come forward with very similar educational qualifications and the eulogies of pedagogues; a handful of deans, with or often without committees, bestows largesse and selects the doctors of tomorrow. For selection it is, and this selection is new. Twenty-five years ago, medical students could gain admittance at will to a medical school, almost always the first they chose. The very fabric of our profession is changed; it no longer selects itself; it has become to that extent anonymous.

ANONYMOUS SERVICE AND MASS MEDICINE

Anonymity, however, is not always, not necessarily vicious. If I seek an expression today of all that is best in the development of group interests, if I seek encouragement in this Freud-bespattered age for confidence in human decency, if I seek assurance that charity is not always imposed by the Welfare State on donor and recipient alike, I find it in fullest measure in the miracle of the blood-transfusion service. Was there ever so exquisitely anonymous, so touchingly charitable a manifestation of man's consciousness of his common interest and indebtedness? For all his conquests, frail man lies in his sickbed a mendicant; shall we not be proud that, in this country, and first and foremost in this country, he may beg of his brother's life-blood, and has never yet been refused? And that blood is given to king or criminal anonymously; none asks whence it came or whither it goes. It is through our hands, as clinical pathologists, that this kindliness finds its channel; last year over 500,000 calls were made on donors, and over 500,000 issues of blood were made; no thanks were sought, and none were given.

---

* Presidential address to the Association of Clinical Pathologists, delivered on Oct. 3, 1952.

If I select this service as the prime example of group consciousness and anonymity in medicine, it is only because it is so widespread and so peculiarly personal. I know well that in the vast sphere of medical research, for example, the same unambitious devotion is manifest; and indeed that in all medicine, in nursing, and in all ancillary branches, the lesson is to be learned that technique is kindliness, and kindliness a technique. We, the doctors, supported now largely by the State, are our fellow-man's expression of his kinsmanship with the Good Samaritan. We are the agents: the bequest was another's.

Indeed, the greatest services, viewed by results, are those which medicine gives broadcast—such services as control of the purity of water-supplies. To a very remarkable degree the health of every member of the community is protected by technique over which the individual has no control, and concerning which the majority are quite ignorant. The most rabid opponent of the bacterial theory of infectious disease is still forced to drink chlorinated water; pasteurisation of milk is imposed even on Christian Scientists. No-one but a crank would seek to restrict the control of infection in this way, or to oppose the hundred-and-one safety measures of the M.O.H. There are limits, however, to the extent to which men may properly be doctored in spite of themselves. A diet deficient in iodine might properly be adjusted by its addition; but can we extend this indefinitely to include, for example, fluorine? If, to push the question to absurdity, authorities supposed that we were becoming effeminate, could we approve the addition of testosterone to margarine as we already approve the addition of vitamins? Health authorities may rightly keep undesirable things out of food and water; how much may we legitimately put in?

We must never forget that opinions tend to change with regard to the harmlessness of materials. When I was working with resorcinol in connection with air sterilisation, I was assured that it might safely be used to sterilise the air of cinemas without the consent or even knowledge of the public; but we have since learnt that it is far from inactive in the human body. Insecticides are used more and more in control of insect life, yet they are not always without action on man. I would hazard a guess that sooner or later—so complex is the allergic state—some person will be found to react unfavourably to almost any substance, organic or inorganic. I am sure that health authorities are fully alive to these considerations; I merely restate an obvious truism that men should only be doctored at their own consent and that nothing should be administered universally until it is overwhelmingly and universally approved.

THE DOCTOR'S CONTRIBUTION

For the greater part of medical history doctors had little or no effect on vital statistics; it would have made no difference to the average survival of the people if there had been no doctors at all. That is, not to say that the doctor had no function; in the relief of anxiety and pain, in prognosis and the ordering of men's lives, and above all as a support, however frail, in times of stress, he has had the same functions at all times as he has now. Moreover, it is by the study of disease through centuries barren of therapeutic discoveries that we today have so largely conquered acute and infectious disorders. But until the time of Pasteur and the triumphs of the laboratory the doctor was fortunate in not being paid by results: it was Pasteur who paved the surgeon's road from tradesmen's entrance to the House of Lords. If some lives were saved by the arrest of hæmorrhage and relief of asphyxia, how many others were lost by infection conveyed by surgeon and midwife?

Indeed, though medicine is often blamed for the over-[illegible]tion of the world, the enormous spurt in population began before doctors had any effective remedies, and was the direct result of the Industrial Revolution. The most overpopulated areas, such as Egypt, are the least doctored. On the other hand, in Western countries it does undoubtedly make a difference to the individual today whether or not he visits a doctor. The doctor now has more to offer than a bedside manner—which probably accounts for his modern sartorial insignificance. It is therefore inevitable that there should be an element of conflict between the doctor's sense of his duty to the community, in acquiring new knowledge, and to the individual, in facing that individual's personal and immediate emergency.

EXPERIMENT AND VOLUNTEERS

New knowledge in medicine must come by the scientific method of trial and error, by experiment. Much of that experiment can be carried out in test-tubes, with no victim more highly developed than bacteria, in whose interests no societies appeal. Much is carried out on animals, and this does pose an ethical problem which not all men answer alike. However, rightly or wrongly, we pathologists accept animal experiments as a necessary evil, realising that far too much of human choice is the selection of the lesser of two evils, and believing, selfishly enough, that relief of human pain is properly purchased at the expense of the animal.

But, sooner or later, knowledge must be applied to man, and need arises for experiment on man. I imply by the word "experiment" that the result of the doctor's intervention is not and cannot be assured, and that it may not be beneficial to the particular patient. Quite often it must be carried out on healthy men; we must ask for volunteers. When we do, let us be quite sure what we mean by volunteers. Obviously an infant or a child cannot be a volunteer, and this places a responsibility on the pædiatrician. In law, certain lunatics may be volunteers; for the law recognises the power of choice in certain aberrations of mind. In other classes of mental ailments all power of choice lapses and no question of volunteering remains. In other ages and countries experiments on persons of unsound mind have been performed, and published without reserve, but in this country and in this age such an approach would be intolerable. We must remember how recently, and not far away, the grossest excesses were perpetrated on sections of the community because an inebriated generation had conceived that that section was deprived of human privilege. We and they have awakened from that nightmare; but there is only one safe rule—no action of a doctor must have any other objective save the individual's personal welfare, without that individual's entire and competent approval. I have the most complete confidence, based on intimate and personal knowledge, in the integrity of the medical services of the Armed Forces in such matters; but, particularly now that service is compulsory for all, they must be prepared to resist any tendency to find a useful reservoir of clinical experiments in this group of healthy young men—especially since, in a disciplined force, the "volunteer" can easily be encouraged by sanctions or privileges. Similar considerations should influence us in approaches to undergraduates or medical students. No scientific doctor should ask another to "volunteer" for measures in which he does not share; and I must admit to the curiosity with which I always seek, in publications, for evidence that the writer satisfied his curiosity, in the first instance, on himself.

An extreme example of pharmacological assay may be offered as displaying methods today obsolete. Curare is now titrated by observing its power to destroy the tone of neck muscles in the rabbit; but its original discoverers were ignorant of this physiological action, and were forced to alternatives. Elderly women were therefore collected and put in prison in a hut with the boiling drug; if they died the curare was accepted as being of optimal strength. This experiment has much in common with contemporary methods except that nowhere on earth would it be done in exactly that way.

Again, an experiment may be entirely legitimate at one stage in our knowledge, and as certainly unethical at another. In the early days of vaccination for smallpox, vaccinated patients were challenged by inoculating smallpox virus. This was, however, entirely proper since the experiment was performed at an institution founded to inoculate smallpox prophylactically; contemporary criticism would have been directed at the vaccination. The experiment failed in matters of detail and as scientists we should much like to repeat it today; but as doctors, indeed as civilised men, we are prevented. Indeed there are many routines in medicine, such as the use of rabies virus in prophylaxis, which are of very doubtful value; yet we can never test their validity since there is evidence (of a kind) of their efficiency.

As an example of an outmoded technique, we may recall that Alfred Donné attempted to establish the significance of vibrios in syphilitic ulcers by human experiment, injecting pus into one leg and pus treated with vinegar into the other. It is in fact remarkable how irresponsibly attempts were made at the end of the last century to produce venereal disease experimentally. Urethritis was produced with pure cultures of the gonococcus in both men and women by at least five separate workers. It is hard to believe that they were not aware of the implications both to the human beings infected and to their children. Human experiments with the cholera vibrio have been, so far as I know, in the best tradition of medical ethics; for von Pettenkofer and Emmerich used themselves for the test, and Emmerich contracted a severe attack of cholera. It is only fair to doctors as a whole to say that as a general rule they have submitted themselves to experiments which they have performed on others. I recall a distinguished laboratory chief who put not only himself but the whole laboratory staff out of action for a fortnight through an unfounded confidence in the nature of his test reagent.

It is right that we should cease to dwell on the horrors of the last war. War is a kind of intoxication, and nations, like men, must be evaluated when sober. I once met a lawyer who held office during the prosecution of Germans for war crimes, and asked him how a nation so renowned for its humanitarian services could have perpetrated such horrors. "There is only one step to take," he answered. "You may not think it possible to take it; but I assure you that men I thought decent men did take it. You have only to decide that one group of human beings have lost human rights."

How far medical experiments were performed on human beings in the late war will probably never be known, for many of the records are said to have been destroyed. Some evidence appears to be fully authenticated—for example, experiments at Buchenwald on typhus inoculations.

> Ninety beds were set aside for experiments; and in the midst of extreme squalor and starvation these were maintained at the ordinarily high level of hospital amenity. Diet was liberal and nursing attentive.
>
> A proportion of the patients volunteered for admission either as a deliberate method of suicide or as a desperate gamble which would at least ensure good food and comfort for a short time. Others were forcibly admitted as criminals or political prisoners. In all, just under one thousand persons were accepted as a study in experimental typhus fever contracted by intravenous inoculation with blood taken on the fifth day of the disease from other patients.

Germans are pedantically careful people. I have read the account of this experiment and as one who has seen this type of epidemic I have no idea why it was carried out, for it seems to have proved nothing not previously known about typhus. But it does prove that under quite extreme, and it may be hoped, unique conditions, human beings may treat each other as animals. We should not forget that he who condemns his brother condemns himself. There but for the Grace of God go we. That ghastly experiment will have had one good result if we only remember that it was in fact carried out.

CONTROL PATIENTS

In test-tube or animal experiments the control test presents no ethical problem. In fact we rack our brains in an attempt to ensure that every possible variant is kept constant save one; I remember a biologist at Cambridge who always recorded barometric pressure, although his experiments were usually on staining methods. But when we come to the human being, the dilemma of the control test is very real. If, for example, we study the cerebrospinal fluid in disease how are we to establish its state in health? If we remove a portion of liver—a procedure not without risk—in order to study hepatitis, with what norm shall it be contrasted? If we think we have discovered a useful treatment, are we justified in withholding it in selected cases and thereby perhaps risking life?

Many will remember that this is the central problem of the novel *Martin Arrowsmith*—perhaps the best fictional study of laboratory life ever written.

Actually, in the early stages of great discoveries the scarcity of the new agent supplies only too many controls. When penicillin reached us in the Middle East we had less than a million units to dispense, and the question was quite literally which of hundreds of dying men were to be selected for survival. A similar problem was treated dramatically by that talented bore Bernard Shaw in *The Doctor's Dilemma*; it is in very truth a fact that the choice between life and death is today in a pathologist's hand every time a new therapeutic agent emerges. The choice is not in practice difficult: for the least likely to survive are selected, thus satisfying both ethical and scientific requirements. One must admit to some concern at the fact that in Britain new discoveries from the dollar countries are often limited at first to those who can pay for them. But there is always a chance that they may be less harmless than is imagined, and in this case it is the rich who are the guineapigs.

I recall an occasion in the late war when a very limited amount of typhus vaccine was made available by the American manufacturers for civilian distribution during a typhus epidemic. My own view was that it should be given to armament-workers and other men of importance in the prosecution of the war; my American colleague insisted that it should be distributed without regard to age, sex, race, or occupation. He won; but as a result we were left in complete ignorance of its protective value; and I myself remain uncertain of its efficacy.

The use of antitoxic serum is still considered imperative in dangerous infections, such as diphtheria and tetanus, where antibiotics are of little value. Indeed to omit their use in a diagnosed case would evoke full medicolegal sanctions. No-one today, therefore, would dare to treat alternate cases with and without antitoxin; but when diphtheria antitoxin was first introduced, and none could surely predict its value, such an experiment was done. This was in my opinion quite legitimate and probably inevitable owing to shortage of supplies. In "Topley and Wilson" the results of this experiment rightly rank as some of the most important evidence for the value of antitoxin. Personally I should much like to repeat it for I am far from satisfied of its validity. But this would be quite impossible; antitoxin does little harm, if any; and to withhold it might be fatal.

The case of rabies is even more remarkable. Many persons bitten by rabid dogs do not get rabies; many who get antirabic treatment die of rabies none the less. But who dare refuse prophylaxis in a disease always fatal?

We are really faced with this problem every day. Medicine can never become fully scientific unless it becomes completely inhuman.

As clinical pathologists all our work, without exception, is a research. Slowly—often, I must admit, with exquisite boredom; often, I proudly claim, with the keenest intellectual pleasure—we collect accurate data from human sources. One objective must inspire our every action—that the interest of the patient must in some way be served by our intervention, unless it is explained to him, without possibility of misunderstanding, that we are seeking not his own welfare but the long-term welfare of humanity. I repeat that all research involves controls: by definition the test on the control cannot possibly be in that individual's immediate interest. It is true that in the ordinary man and woman there is a lordliness which will nearly always give generously of discomfort or even pain when asked to share with us the privilege of our voyage into the silent sea of knowledge. Our proud and angry dust has always found in self-sacrifice its challenge to a hostile universe. But what we may humbly ask we may not arrogantly demand; and I think that it is here that the conflict between our duty to the individual patient and to the whole sad host of human misery presents itself most clearly to the pathologist.

The possibility of transgressing this rule has been made more plausible not only by the increasing application of scientific methods to medicine but by two other factors—the independence of the doctor from private practice and the increase in academic appointments. So long as a doctor's pocket suffered by undue attention to herd interests, his scientific aspirations were held on a tight rein. As for academic appointments, it is difficult to wear any uniform without sooner or later feeling that one must live up to it. The Salvation Army lass reaches for her tambourine, the general for his sword (or perhaps in these days for his telephone), and the professor of medicine, surgery, or pathology for his fountain-pen. But let us not delude ourselves; the more we emphasise the academic aspects of medicine the more closely we must watch the interests of the individual patient.

EXTENSION OF LIFE

I have spoken of the doctor as the agent of his countrymen in the fulfilment of their philanthropic instincts. In these activities he is not given complete freedom. However much the pædiatrician may be tempted to practise infanticide it is forbidden; euthanasia may be advised, but it may not be instituted. In other cases what the law permits individual religions do not; contraception and sterilisation are examples.

There are some problems of great complexity on which neither State nor Church ventures to rule, but which the doctor must none the less face. At what price may extension of life legitimately be inflicted on a patient? Life is an incurable disease, as Oliver Wendell Holmes said, and always ends fatally; but is mere length of days, however dread the burden, to be sought? I have said that doctors are unfairly blamed for the over-population of the world; but the doctor must bear his share of blame for longevity, that second curse of mankind today. It is science as a whole which pleads guilty to overpopulating the world while underfeeding it; but medicine stands accused of making old age possible before making it endurable. In part I think a valetudinarian age must share the blame; the citizens of the second Elizabeth contrast strangely with those of the first, and life is a journey which nowadays many people finish with too much petrol in their tanks.

In no period has length of days been considered in itself a proper aspiration, and indeed the time when desire shall fail and the grasshopper be a burden is as much a reality as ever. I have often wondered what specialty Shakespeare would have chosen had he been a doctor of today. But certainly the author of *King Lear* would never have taken up geriatrics; and when I see what modern medicine does for the aged, I recall his words "O! let him pass; he hates him that would upon the rack of this tough world stretch him out longer."

The patient meets his doctor with a very wide mandate. He is anxious, and seeks peace of mind; he is in pain, and seeks relief; with the prospect of death, he asks reprieve. But the mandate goes further, and always there is in his mind the unspoken request: "Some time I must die. As a layman, I cannot tell the choice, if choice there be, of my path; but I trust your greater knowledge to see me through in the kindest way."

It is in the management of malignant disease that, to my mind, surgeons and radiotherapists of today are at times wrongly orientated. There is too much emphasis on the remote chance of "cure," too little on the mitigation of the reasonably certain course of the disease. There is some modern surgery which merely ensures that the patient's remaining days will be spent in convalescence from the operation. And there remains always the distressing fact that a patient or his relatives, faced on the one hand by an honest and correct statement that recovery is impossible and on the other by a statement that it may be ensured in certain especially skilled and expensive hands, will sometimes choose a road that is sadly against his interest. The final degradation of medicine is to become the blackmail of the dying with the fear of death.

THE ONLY SIGNIFICANT PROBLEM

During the last twenty-five years the laboratory has dominated medicine in the service of man. But this is only a temporary phase; at one time or another it has been given to physician, anæsthetist, or surgeon, or to the specialist in public health, to hold pride of place; and already the physicist is knocking at the door. (I refer, of course, not to the physicist as radiotherapist; it is the physicist in his exploration of the structure of living matter to whom the future belongs.)

Years ago I met in Jerusalem a very old and learned Jew, and complimented his race on its high proportion of great artists. "You are wrong to congratulate us," he replied. "The artist is always, in each age and race, an honoured guest. Our pride is in our welcome." It is in that spirit, I know, that we rejoice that our branch of medicine has in these last years had such high privilege.

But medicine, and above all scientific medicine, must never forget that in the ultimate analysis the only significant problem is the interest, both immediate and remote, of one frightened patient. Our vague but insistent feeling that humanity's problems are so vast that only vast generalisations can deal with them may lead us to forget that frightened unit. We have inherited a degree of trust more entire than that given to any other group of men—in these days we are trusted more than the priest. If we forfeit that trust by allowing the anonymity of our age to hide the unique personality of the patient, we may learn much and more quickly of the nature of disease, but we shall have lost a friend.

ISONIAZID IN PULMONARY TUBERCULOSIS

ITS USE WITH AND WITHOUT STREPTOMYCIN

After the synthesis of certain thiosemicarbazones and the demonstration of their antituberculous activity by Domagk et al. (1946) a number of similar compounds were made (Fox 1951) and tested against artificially induced tuberculosis in animals. Of these, isonicotinic acid hydrazide (isoniazid) was found to be effective against tuberculosis in mice (Grunberg and Schnitzer 1952) and subsequently in man (Robitzek et al. 1952). These workers wrote enthusiastically of its effects, and the echoes of their remarks reached the lay press in America and this country. A more cautious attitude was adopted by Elmendorf et al. (1952); but they, like the American Trudeau Society, recommended further clinical trials.

A large-scale trial has been conducted by the Medical Research Council which has recently published findings and conclusions after three months' observation (Medical Research Council 1952). The conclusion in this report is that "isoniazid is a very effective drug in pulmonary tuberculosis, but given alone it is not more effective than streptomycin plus P.A.S."

The investigations carried out at Guy's Hospital have fallen into three groups: (1) microbiological studies of the action of isoniazid in vitro (Knox et al. 1952); (2) studies of its efficiency in experimental tuberculosis (Goulding and Robson 1952); and (3) a clinical trial of its effectiveness alone and in combination with streptomycin in a small series of patients with pulmonary tuberculosis. The present paper gives the results of the clinical trial.

METHODS

Clinical trials with isonicotinic acid hydrazide both alone and in combination with other substances were started in March, 1952, and are still in progress. The investigation was made on outpatients who had been attending the Bermondsey and Southwark chest clinics. All patients were sputum-positive and had chronic fibrocaseous disease which in almost every case had been present for many years. Some had had chemotherapy at some stage in their illness, but the effects of this were judged to have ceased and only one instance of definite streptomycin resistance was discovered. Clinically the patients varied from the "good chronic" doing a part-time job who appeared to have achieved an unhappy symbiosis with the organism, to the toxæmic invalid in whom the disease was pursuing a slow but relentless downhill course. All patients attended Guy's Hospital once each week for clinical assessment (C. L. J. and K. S. M.). In addition they were weighed and blood was collected for erythrocyte-sedimentation rate (Westergren). Radiographs were taken before treatment and subsequently at intervals of three or six weeks. These were all examined by the same radiologist, who had no knowledge of what treatment was being given. Each patient submitted three early morning sputum samples each week, and kept a daily record of morning and evening temperatures with standard thermometers which were provided. Initially the plasma levels of isoniazid were measured; but when it was found that satisfactory levels were always achieved, this was discontinued. Similarly urine samples were collected before and after six weeks' treatment. No abnormalities were found; and this, too, was subsequently discontinued. A clinical umpire was appointed (E. K. P.) to whom any patient showing signs of deterioration was referred, and his decision about further treatment was accepted as final.

Bacteriological Methods

Sputum samples were sent to the laboratory in screw-top waxed cartons enclosed in stout envelopes bearing the patient's name. The macroscopic appearance of the specimen was recorded and the volume (scanty or copious) was noted. Films were made from the untreated sputum and stained by Ziehl-Neelsen's method, using malachite green as a counter-stain. These films were examined by one observer (P. J. C.) using a $^1/_7$-in. fluorite oil immersion objective. In each instance 100 fields were searched and the count was expressed as number of tubercle bacilli per 100 fields. All negative films were checked by another observer, and neither was aware which patients were receiving treatment. Thus no specimen was reported as negative microscopically unless 200 fields had been examined. Slides and record cards bore serial numbers only, as a further protection against recognition.

Culture.—Digestion of sputum was carried out by Jungmann and Gruschka's (1938) method. Particular attention was paid to the use of 10 vol. hydrogen peroxide as recommended in their original paper. Digesting fluid was run into each carton from a hooded burette and the mixture transferred to a wide-mouthed universal container for shaking and centrifugation. The deposit was neutralised with one 25 ml. wash with normal saline. Material from each container was inoculated on to three Lowenstein-Jensen slopes and incubated at 37°C for six weeks. Specimens from all patients were cultured thrice weekly for the first six weeks and thereafter, as far as possible, at intervals of three weeks. Cultures were examined at weekly intervals and the results entered on individual record cards. Where single colonies appeared, the numbers were noted as was the number of contaminated slopes. Subcultures were made in Dubos liquid medium for estimating the sensitivity of strains to isoniazid and streptomycin.

PRELIMINARY INVESTIGATION

As no controlled investigation had been reported on isoniazid in tuberculosis in man, a preliminary comparison was made between the effects of this substance and identical capsules containing lactose. 24 patients were selected and carefully paired in terms of age and duration, degree, and progression of disease. 1 of each pair received isoniazid (250 mg. daily in five 50 mg. capsules, one after each meal and two last thing at night, for six weeks) and the other the dummy capsules in the same way. The distribution was made in a random fashion and was unknown to the clinicians. 2 patients defaulted, both of whom were subsequently found to have been receiving lactose.

A clear difference was seen in the progress of the two subgroups, so that the clinical assessors made 19 correct predictions of treatment from the 22 remaining patients. Details of the observations made on the treated group are given later, but the weight changes in the two subgroups are compared in fig. 1.

The sputum from the patients in the treated group showed striking naked-eye and microscopic changes

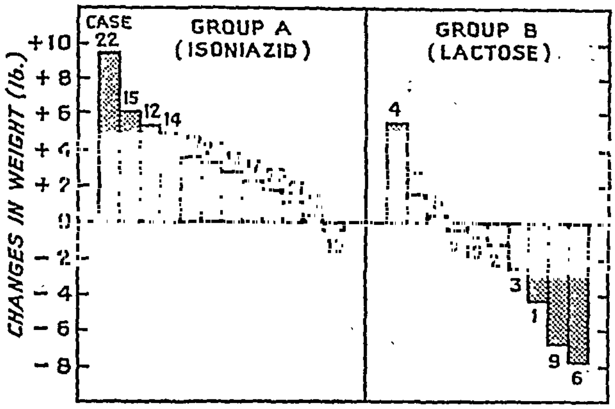

Fig. 1—Preliminary experiment to compare changes in weight in two groups of patients, one receiving isoniazid and the other identical capsules containing lactose for six weeks.

which are described more fully later. No such changes were seen in the control group.

During this period plasma levels of isoniazid were determined by the method of Rubin et al. (1952). Estimations made during the first three weeks of treatment showed levels between 2·0 and 0·79 µg. per ml. in the patients receiving the drug. As therapeutic concentrations were clearly being achieved on the dosage administered, further estimations were considered unnecessary.

THE MAIN TRIAL

This preliminary investigation showed clearly the effectiveness of isoniazid over a short period. It seemed important to investigate next whether this effect continued during longer periods of treatment and whether the drug was most effective alone or in combination with streptomycin. Accordingly, after the preliminary six weeks the patients who had so far served as controls, together with 1 newcomer, were given isoniazid in the same way, and also streptomycin 1 g. six days a week intramuscularly. The trial was conducted as before, and the results obtained during the first eighteen weeks of treatment in each group have been compared.

The Groups

Group A comprised 12 patients (3 women and 9 men), aged 25–49 years, who received 250 mg. isoniazid by mouth daily.

Group B comprised 11 patients (4 women and 7 men), aged 21–58 years, who received isoniazid in the same way, and also streptomycin sulphate 1 g. intramuscularly on six days of each week.

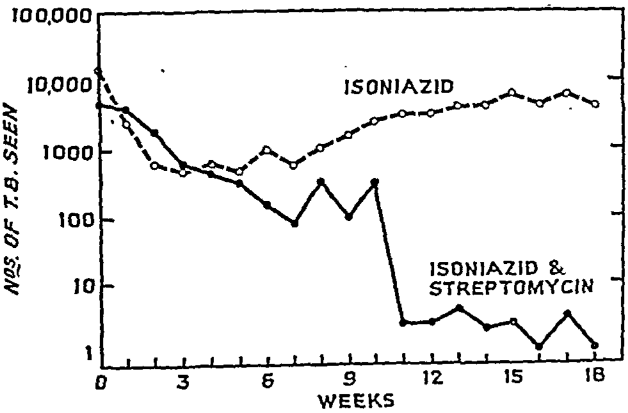

Fig. 2—Changes in excretion of tubercle bacilli in the sputum of patients in group A (isoniazid alone) and group B (isoniazid and streptomycin). (For explanation see text.)

Owing to an administrative difficulty, group B (with the exception of the newcomer) received isoniazid alone for the first of the eighteen weeks during which observations were made. Only on 11 occasions were weekly appointments missed, and when this occurred a mean value was taken from the readings obtained at the prior and subsequent attendances. As this was necessary only once in 40 values, it has been disregarded as a source of error.

Clinical Results

Between the first and the sixth week there was a striking clinical improvement in both groups. Attention is especially directed to the increased sense of well-being and better appetite which almost all patients enjoyed. The cough improved in a uniform way. It first decreased in frequency and severity, and then the sputum became less. Only 2 patients in group A and 4 in group B were pyrexial; and in 5 of these 6 patients the temperature was restored to normal. The remaining patient (in group B) had chronic bronchitis, which was thought to be causal. 2 other patients in group A who had previously had normal temperatures showed mild and transient pyrexial reactions for two and three days immediately after starting on isoniazid. No patient in either group noticed any increased frequency of hæmoptysis.

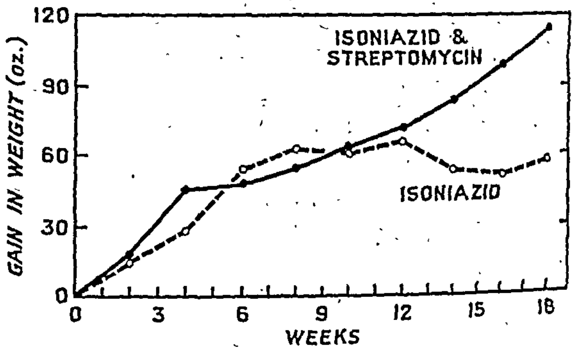

Fig. 3—Mean (cumulative) weight changes, recorded fortnightly, of patients in group A (isoniazid alone) and group B (isoniazid and streptomycin).

This improvement was maintained in group B throughout the eighteen weeks' observation period, and at the end of the course all the patients said that they had felt themselves improving progressively all the time. In group A, however, most of the patients said that they had noticed most improvement in the first half of the course, and 4 felt that they were relapsing during the last part. Another patient (fig. 7, no. 15) improved spectacularly until the eleventh week, and then relapsed so acutely that she had to be withdrawn from the trial at sixteen weeks.

Radiographs

At the end of eighteen weeks in group A 2 patients had improved and 2 were worse; 8 remained unchanged. In group B 4 had improved and 7 remained unchanged.

Sputum

Successive specimens of sputum from the patients in both groups showed at first a progressive change in macroscopic appearance. In addition to a decrease in volume the physical characteristics altered considerably. For example, some specimens changed from purulent to mucoid and finally became salivary, while others decreased strikingly in volume and their tenacious consistency resembled that of the sputum in acute lobar pneumonia. In later weeks, however, in the sputa of group A there was a progressive relapse in physical properties with a return to the original volume and purulent characteristics. In group B, on the other hand, the improvement was maintained.

WEIGHT CHANGES (IN OUNCES) IN GROUPS A AND B OVER EIGHTEEN WEEKS

Group A (isoniazid alone)				Group B (isoniazid plus streptomycin)

* Twelfth to sixteenth week only (withdrawn).

The bacillary count per 100 fields in three specimens from each patient was totalled to give an estimate of the weekly excretion of *Mycobacterium tuberculosis*, and the mean number per patient was plotted on a convenient scale against time in weeks. Fig. 2 gives the mean number of tubercle bacilli found per patient in the two groups. The transitory fall shown by group A is in striking contrast to the persistent fall shown by group B. Figs. 6 and 7 include the sputum-counts of individual patients. It was already clear by the third week of treatment that most cases in both groups were showing a striking fall in bacillary count. It can be seen, however, that in group A by the sixth week some patients were already showing an upward trend in their graphs. This occurred at the same time as the naked-eye relapse mentioned above and continued in later weeks. In group B, on the other hand, the initial fall in the sputum-count was maintained, apart from an occasional "flare-up," to the end of the eighteen-week period.

Culture of Myco. tuberculosis

All the patients in groups A and B supplied specimens of sputum in the pre-treatment period, except case 11. We do not propose to discuss the cultural results in detail here; but whereas in the pre-treatment period positive cultures were obtained without difficulty, in specimens from patients receiving isoniazid either alone or with streptomycin the proportion of successful isolations became less during the course of the trial.

For this and other reasons our information about the development of resistance in patients receiving chemotherapy is rather scanty. Cultures from 22 patients (12 from group A, 10 from group B) were tested for sensitivity to isoniazid and streptomycin at the start of the trial. All of these were sensitive to 0·1 µg. per ml. of isoniazid or less. Of the 22 cultures 1 was resistant to more than 10 µg. per ml. of streptomycin, 3 were sensitive to 1 µg. per ml., and the remainder were sensitive to 0·4 µg. per ml. or less. During treatment, in group A 2 out of 11 patients in the fourth week and 5 out of 6 patients in the tenth week had produced strains resistant to 0·1 µg. per ml. or more of isoniazid. Their resistance to streptomycin was unchanged. In group B in the fifth week 5 out of 5 patients produced cultures sensitive to 0·1 µg. per ml. of isoniazid and streptomycin.

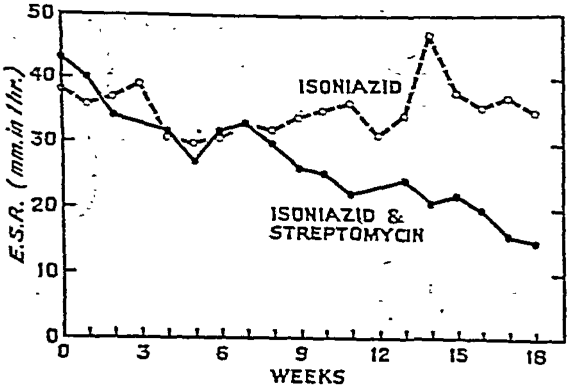

Fig. 4—Mean weekly erythrocyte-sedimentation rate in group A

Weight

The weights were recorded weekly. Fig. 3 shows the average gain and loss in ounces of each group over each fortnightly period of the trial. This graph shows that whereas the isoniazid group failed to gain weight after the eighth week, the group treated with streptomycin in addition showed a steady gain throughout the whole period of the trial. Case 15, a patient who was losing weight rapidly and who was unfit to continue in the trial after the sixteenth week, is not included in the average for the final fortnight.

That the difference between groups A and B is not due to a very large change of weight in one or two cases is well shown by the accompanying table, which gives the weight change of all cases over the first, middle, and final six-weekly period of the trial. In the final period 3 cases in group A gained, and a similar number lost, 2 lb. or more; while in group B 7 gained, while none lost, this amount. This is in strong contrast to the initial period, where the two groups show a striking similarity, 8 patients in each gaining, and none losing, 2 lb. or more.

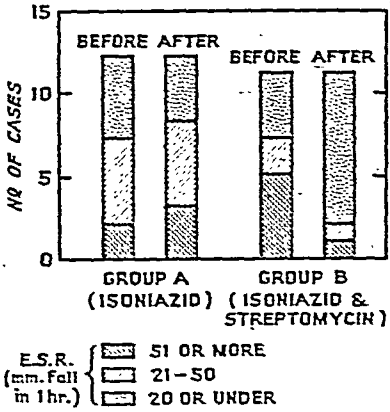

Fig. 5—Distribution of high, moderate, and low erythrocyte-sedimentation rates in the two groups before and after the trial.

The weekly weights of these 23 patients are shown graphically in figs. 6 and 7. In group A, case 22 gained weight rapidly throughout; case 15 gained weight rapidly at first, but in the last six weeks her weight fell precipitously and she was withdrawn from the trial; case 12 behaved similarly, but the fall was not quite so severe. Cultures from both these last 2 patients developed resistance to 10 µg./ml. of isoniazid at about the fifth week of treatment. In group B, the greatest gains in weight were shown by patients 1, 6, 9, and 10, all of whom were losing weight during the seven weeks before treatment started (fig. 1).

Erythrocyte-sedimentation Rate

Mean weekly values are shown in fig. 4. Case 15 was withdrawn at sixteen weeks. This figure shows that the value for the erythrocyte-sedimentation rate (E.S.R.) fell in both groups until the fifth week, after which this tendency ceased in group A. In group B it was maintained throughout the eighteen-week period.

That this difference is not accounted for by one or two cases showing very large changes in the sedimentation-rate is shown in fig. 5. Here the number of patients in each group having high (51 mm. +), moderate (21–50 mm.), and low (under 21 mm.) sedimentation-rates at the beginning and end of treatment is shown graphically. The weekly E.S.R. for each of the 23 patients

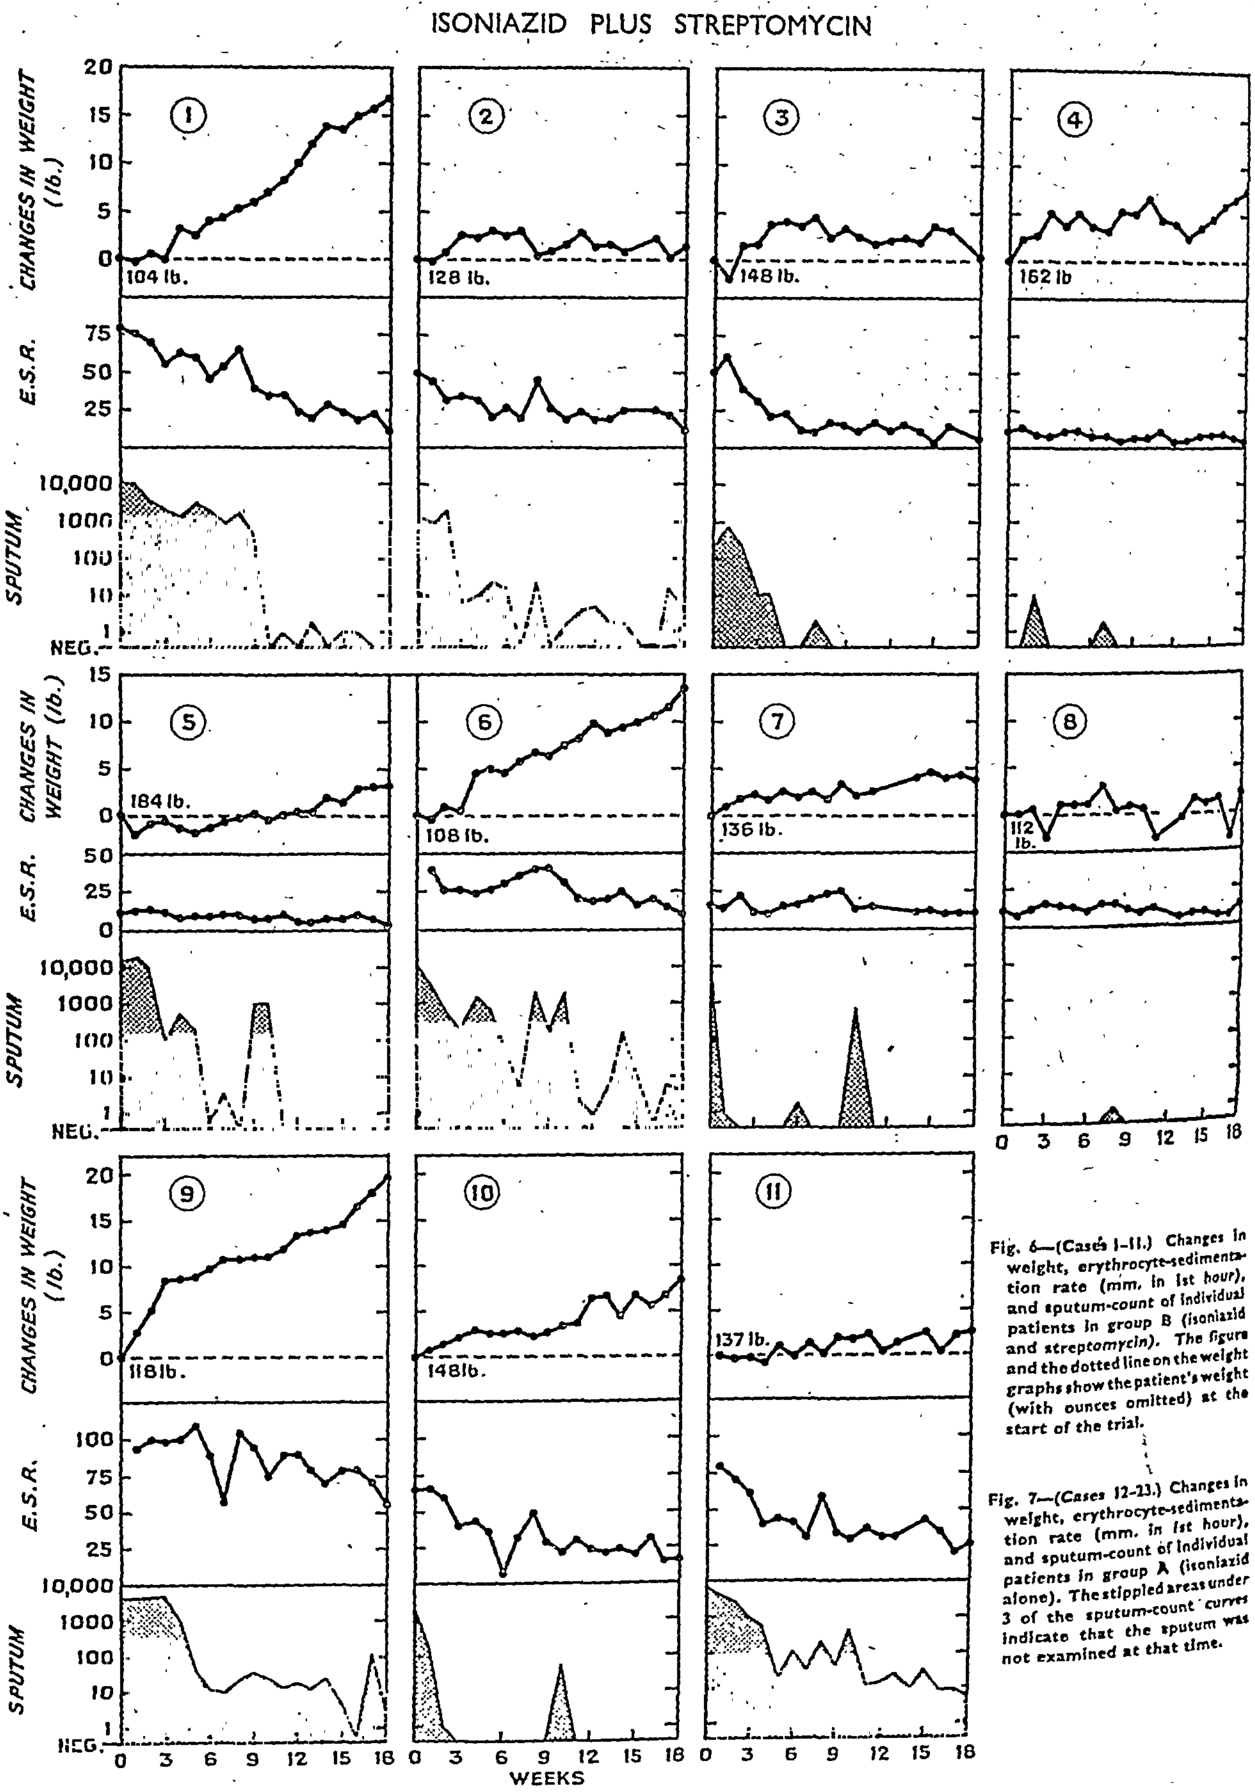

Fig. 6.

Fig. 6—(Cases 1-11.) Changes in weight, erythrocyte-sedimentation rate (mm. in 1st hour), and sputum-count of individual patients in group B (isoniazid and streptomycin). The figure and the dotted line on the weight graphs show the patient's weight (with ounces omitted) at the start of the trial.

Fig. 7—(Cases 12-23.) Changes in weight, erythrocyte-sedimentation rate (mm. in 1st hour), and sputum-count of individual patients in group A (isoniazid alone). The stippled areas under 3 of the sputum-count curves indicate that the sputum was not examined at that time.

ISONIAZID ALONE

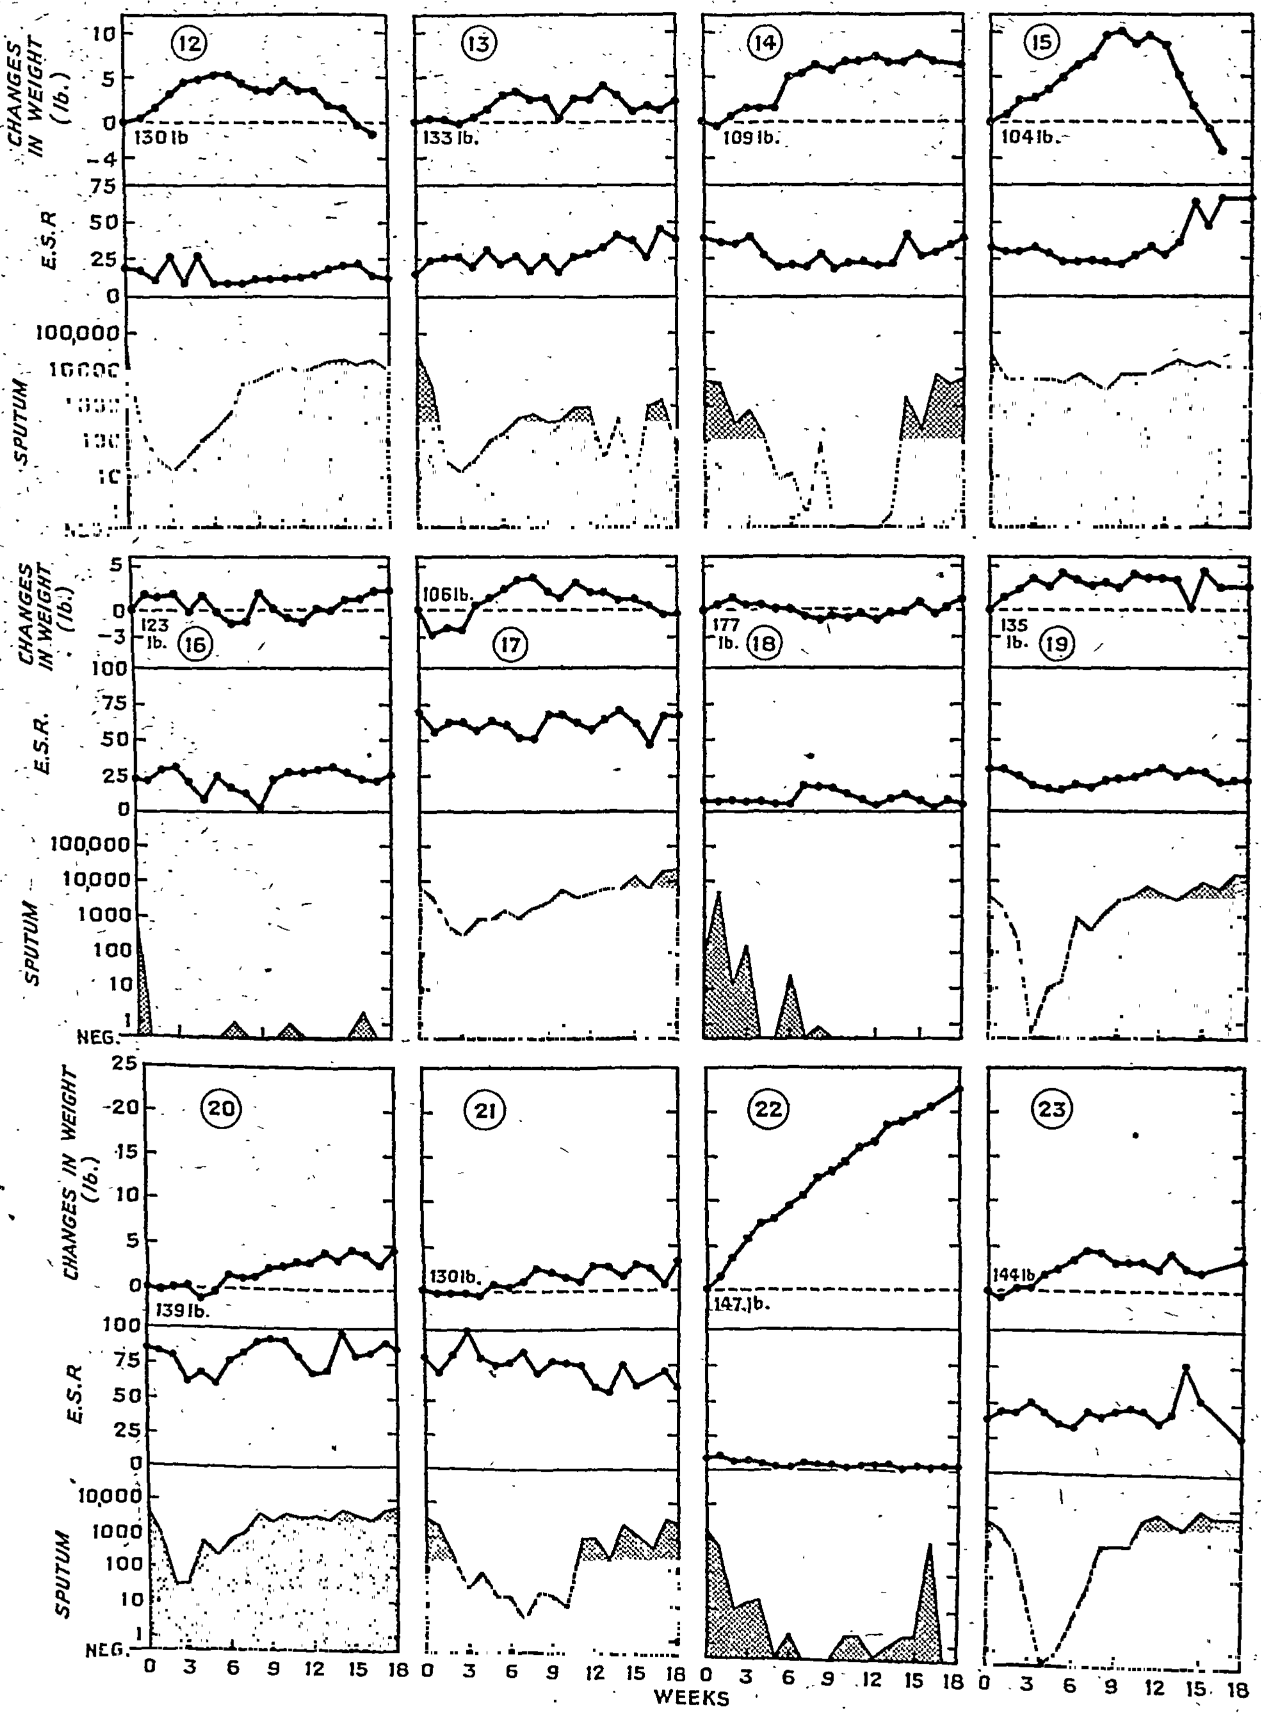

Fig. 7.

Toxicity

No patient noticed any subjective toxic reaction to isoniazid. One observer (K. S. M.) thought that after about six weeks some hyperreflexia was present, and that it persisted throughout the course. In group B 3 patients developed rashes between the thirteenth and eighteenth week. In 1 case this was so severe that the dosage of streptomycin was reduced to 1 g. three times each week in the last two weeks.

COMPARISON WITH STREPTOMYCIN AND P.A.S. THERAPY

It seemed clear that patients on isoniazid plus streptomycin had fared better than those on isoniazid alone. It was now important to ascertain how this form of combined treatment compared with the well-tried combination of streptomycin plus *p*-aminosalicylic acid (P.A.S.). Two groups of paired patients—group C (9 patients given isoniazid and streptomycin) and group D (9 patients given streptomycin plus P.A.S. plus lactose)—were investigated. In group D, of the original 9 patients, 1 defaulted and in 1 treatment was stopped because of a reaction to streptomycin. That trial, and certain others, will be reported fully at a later date, but certain interim results, given below, appear pertinent.

Weight

The mean weight gains in groups C and D were as follows:

Group	*Weeks* 0–6	*Weeks* 6–12
C (9 cases)	4 lb. 9 oz.	3 lb. 10 oz.
D (7 cases)	2 lb. 8 oz.	1 lb. 12 oz.

Sputum

In both groups the sputum-counts fell at about the same rate, and this improvement was maintained.

E.S.R.

The mean E.S.R. values (Westergren, mm. in first hour) were as follows:

Group	*Weeks' treatment* 0	6	12
C (9 cases)	61	28	21
D (7 cases)	75	37	28

The E.S.R. in both groups showed approximately equal improvement.

DISCUSSION

The number of cases reviewed in this report is small, and the results do not therefore lend themselves to detailed statistical analysis. Nevertheless, the data obtained from each case were considerable. Clinical assessment, erythrocyte-sedimentation rate, and body-weight were recorded weekly by the same physician; and specimens of sputum from each patient were examined twelve times each month, so that the criterion for a negative microscopic result was strict. In this way it was possible to compare very accurately the progress of patients receiving different treatment.

The investigation is only concerned with patients with chronic pulmonary tuberculosis corresponding to group 3 in the Medical Research Council (1952) trial. It might be expected that such patients would do worse than those with the more acute early pulmonary lesions, and that the problem of resistance would be at its maximum.

The patients were drawn from working-class homes, and all were treated as outpatients. Thus the conditions of the trial were those under which most patients with this type of disease have to be treated today. Great hopes had been entertained that isoniazid would prove of immense benefit in this type of case, and it was with a view to providing some information on this all-important question that this investigation was planned.

The method of pairing cases and including one of each pair in each group ensured that groups A and B contained very similar clinical material. Owing to the preliminary experiment during which group B received lactose capsules for a total period of seven weeks, we know that most of these patients were losing ground when treatment with isoniazid and streptomycin was started (see fig. 1). The rapid clinical improvement in pulmonary tuberculosis after administration of isoniazid is now well established. This effect was demonstrated conclusively during the initial period when group A received isoniazid and group B lactose-capsules, and will not be discussed further here.

Comparison between the effect of isoniazid alone and isoniazid plus streptomycin over an eighteen-week period is, however, of great interest. While there is little difference in the progress of the two groups during the first half of the course, a great change becomes apparent after the twelfth week. The majority of patients receiving isoniazid alone deteriorated during the last six weeks of the course. This was shown by a return of tubercle bacilli in the sputum, cessation of weight gain, and in several cases weight loss; while the erythrocyte-sedimentation rate, which had in most instances undergone a moderate improvement, returned to the original level. Of 12 patients 5 realised that they were losing ground, but with 1 exception all thought they were better than before treatment. It was our impression that the subjective sense of well-being continued after the disease, as judged by sputum examination, erythrocyte-sedimentation rate, and weight change, had recrudesced to its former level. Mention must be made of case 15. This patient who was initially the most severely ill of the group made a spectacular improvement for eight weeks. Her temperature settled and she had put on over 9 lb. in weight. From the twelfth to the sixteenth week, however, the disease again became extremely active, her weight fell by 12 lb., and her temperature rose to a higher level than before treatment. On the other hand, all patients receiving streptomycin in addition to isoniazid improved steadily throughout the eighteen weeks.

A further series of 9 patients receiving isoniazid and streptomycin have now been followed to fourteen weeks. Again steady improvement has continued. This series (C) was not strictly comparable with group B as it contained a higher proportion of more toxic patients. The weight gain, while following the same steady increase throughout the fourteen weeks, was nearly double that observed in the first fourteen weeks in the group-B cases.

This discrepancy is of interest. Weight gain in tuberculous patients treated with isoniazid must depend upon two factors—namely, the increase in appetite consequent upon the disappearance of *toxæmia*, and the amount of food available for the patient to eat. Our patients had not access to the colossal diets available to the first cases described at the Sea View Hospital, New York, and so the weight increase tended to be more modest. Nevertheless, while it is possible that group C had slightly better home conditions than group B, the difference, if any, was small and cannot be held to explain the very pronounced variation between the two groups. The explanation probably lies in the greater toxicity in group C before treatment was started (E.S.R. average: group C 61 mm., group B 43 mm.). It is likely that patients in group C had suffered greater weight loss in the period immediately before treatment, and so gained weight at a greater speed when the toxæmia was removed. This emphasises the great importance of ensuring that groups to be compared should consist as far as possible of patients whose disease is in a similar state of activity as well as having comparable radiological appearances.

The remaining patients in group D, who have received streptomycin and P.A.S. for fourteen weeks, have shown a steady increase in weight although of very much smaller degree than was seen in group C. Nevertheless they have gained weight at almost as great a rate as group B. We consider that as they were extremely toxic at the beginning of treatment (E.S.R. average 75 mm.) the comparison with their paired group C is valid. Since groups C and D were both receiving the same dose of streptomycin, the results suggest that the greater increase of weight in group C was due to the isoniazid and thus indirectly support the conclusion reached in the Medical Research Council trial that isoniazid does cause an increase in weight not seen in patients treated with streptomycin and P.A.S. The improvement in the sputum and erythrocyte-sedimentation rates was of about the same order in groups C and D. The combination of isoniazid and streptomycin also has the advantage that patients find isoniazid easy to take, and it does not cause the nausea characteristic of P.A.S.; but larger series will have to be treated over a longer period before it can be certainly established that isoniazid plus streptomycin is in all respects the equal of P.A.S. plus streptomycin.

The important feature of this trial at the present time would seem to be the observation that most patients who receive isoniazid alone regress after a period of eight to ten weeks. This regression is associated with the development of isoniazid resistance. It is too early to be certain whether streptomycin prevents this resistance to isoniazid, or whether isoniazid acts like P.A.S. and the beneficial effect seen in the later weeks of an eighteen-week course of isoniazid and streptomycin is due to the fact that the tubercle bacilli remain sensitive to streptomycin.

These results suggest that the haphazard use of isoniazid alone in treatment of chronic pulmonary tuberculosis must be strongly condemned. There is a grave risk that the last state of patients treated with isoniazid alone may be worse than their first and that they will transmit isoniazid-resistant organisms to others. On the other hand there is no doubt at all that isoniazid, initially at least, hits the tubercle bacillus both in vitro and in vivo in a particularly vulnerable spot. It may be possible to find some modification of the molecule which will overcome its gravest disadvantage—the ease with which resistant strains develop. At present there is no doubt that this disadvantage can be greatly lessened by at least one form of combined therapy. While it may be that in time patients receiving streptomycin and isoniazid may become resistant to both before the sputum can be rendered permanently negative, this combination is apparently very effective and deserves much further trial.

CONCLUSIONS

Certain definite conclusions can be drawn from these results:

1. Isoniazid alone has a beneficial effect on certain cases of pulmonary tuberculosis in the first three to six weeks of treatment. In the next few weeks the initial improvement is no longer maintained; and soon deterioration ensues, especially at first in the sputum-counts. This deterioration is associated with the excretion of resistant strains of tubercle bacilli in the sputum.

2. Combined therapy with isoniazid and streptomycin, on the other hand, gives a completely different picture when continued for a long enough period. There is the same initial improvement as in the patients treated with isoniazid alone; but the improvement is maintained until at the end of eighteen weeks there is a great difference between the two groups. The initial rapid improvement in the sputum-counts, the gain in weight, and the fall in the erythrocyte-sedimentation rate all continue and there is paralleled improvement in the clinical condition.

We are indebted to Dr. B. J. Malley, chest physician, Bermondsey chest clinic, who allowed us to include some of the patients under his care, and Dr. E. V. Medill, who independently assessed the radiological changes. We should also like to thank Mr. D. E. Seymour, of Herts Pharmaceuticals Ltd., who kindly made available the supplies of isoniazid ('Pycazide') used in the trials. We should also like to thank Miss D. M. Read for her help in organising the clinical aspects of the trial, and Mr. J. A. Hughes and Mr. R. C. Woodroffe for their invaluable help in the laboratory. We should also like to acknowledge the secretarial and other help which we have received from members of the hospital staff and the Medical School of Guy's Hospital.

ISONIAZID IN THE CONTROL OF EXPERIMENTAL CORNEAL TUBERCULOSIS

ROY GOULDING
M.B., B.Sc. Lond
JUNIOR LECTURER IN PHARMACOLOGY

J. M. ROBSON
M.D., D.Sc. Leeds, F.R.S.E.
PROFESSOR OF PHARMACOLOGY

GUY'S HOSPITAL MEDICAL SCHOOL, LONDON

It has been shown that experimental corneal tuberculosis in both mice and rabbits provides the basis of a reliable and rapid in-vivo test by which the antituberculous activity of various chemotherapeutic substances may be assessed (Robson 1944, Gardiner et al. 1949, Rees and Robson 1950, 1951). Following the injection of a standard suspension of tubercle bacilli, the "cornea responds in a regular and prediotable manner." The way in which the natural history of such artificially induced lesions may be modified by treatment of the animals reflects the antituberculous properties of the agents so employed. The results already obtained in this way with streptomycin, *p*-aminosalicylic acid (P.A.S.), and the thiosemicarbazones are, significantly, in accord with clinical observations.

The object of the present investigations has been to ascertain the effectiveness of isoniazid, either alone or in combination with other drugs, in the control of experimental tuberculous infections of the cornea. The opportunity has thus arisen to relate the behaviour in vivo to the properties in vitro as now reported (Knox, King, and Woodroffe 1952) and also possibly to provide experimental evidence in support of the combined drug therapy that has been tested in clinical practice (Joiner et al. 1952).

METHODS AND MATERIALS

The experiments here described fall into two groups. In those with mice the technique followed was that of Rees and Robson (1950) and in those with rabbits the procedure was that of Gardiner et al. (1949).

Mouse Experiments

Albino mice, each weighing approximately 25 g., were subjected to deep anæsthesia by means of bromvaletone and ether. Into one eye of each animal a standard suspension of *Mycobacterium tuberculosis*, comprising about 1000 organisms in a 'Tween 80' medium, was then introduced. Cultures of both human (H37RV) and bovine strains were employed. The latter was supplied originally by Dr. W. M. Levinthal, of the Royal College of Physicians, Edinburgh. It has since been maintained by passage through the mouse, inoculation upon Dorset egg medium, and weekly subculture in Dubos medium containing 'Tween 80' and bovine albumin, up to a maximum of seven subcultures before return to a mouse. Seven-day cultures in the fluid medium formed the basis of the suspensions actually injected.

The developing lesions were subsequently observed at short intervals by the aid of a low-power binocular microscope. In the absence of treatment, the average incubation period is twelve days from inoculation. The corneal tubercles which then appear advance to a maximum at about thirty days, and thereafter undergo spontaneous partial regression until they are ultimately stabilised. In the present series, treatment was always initiated on the first day of the experiment and continued for a definitive period of twenty-eight days. During this time feeding was standardised, M.R.C. mouse diet 41 being offered at the rate of 5 g. per head per day. Initially, also, penicillin was given daily by subcutaneous injection with a view to limiting the secondary infection which occasionally occurred. Isoniazid and P.A.S. (as the sodium salt) were given in the diet, and the streptomycin (as the calcium chloride preparation) was administered daily by subcutaneous injection. The dosages were as follows: isoniazid 0·3 mg. per mouse per day (equivalent to about 12 mg. per kg. body-weight), streptomycin 4 mg. per mouse per day (equivalent to about 0·16 g. per kg. body-weight), and P.A.S. 2% of the sodium salt in the diet (equivalent to about 4 g. per kg. body-weight).

In each instance the course of the disease in the treated animals was compared with that in a control (untreated) group. Note was made of the incubation period, the extent of the lesion (by an arbitrary method of scoring), its rate of advance, and the number of animals involved. Thus a comparison could be made between treated and untreated animals week by week, either according to the percentage in each group protected from the disease or according to the average extent of the lesion in each group. Graphing such figures tended to emphasise any differences.

Rabbit Experiments

With the rabbits, deep anæsthesia was obtained by the use of ether alone and, this time, the standard amount of suspension of *Myco. tuberculosis* injected intracorneally into each eye contained only about 300 organisms. All animals were kept in individual cages and fed on the same diet. The corneæ were examined each week and the extent of the lesion was noted in each case. Again, an arbitrary method of scoring was applied. In the untreated rabbit, such experimental corneal tuberculosis has an incubation period of twelve to fourteen days. From this stage, when minute primary tubercles appear in the needle track, the disease steadily advances, eventually proceeding to panophthalmitis and, in about three months, to generalised tuberculous infection of the animal. The effectiveness of any antituberculous agent can therefore be judged by the degree and rate at which this normal course is modified by treatment.

In one experiment with rabbits treatment was started on the day of inoculation. To one group streptomycin (as the calcium chloride preparation) was given by subcutaneous injection, twice daily, at a dose equivalent to 100 mg. per kg. body-weight per day; and to another group isoniazid similarly at the rate of 10 mg. per kg. body-weight per day. Treatment was maintained for eight weeks in all. In the second experiment with rabbits, treatment was not initiated until moderately advanced lesions had already become established. Then, streptomycin was given to one group, isoniazid to the second, and the two drugs together to the third, in each case at the dosages already stated.

RESULTS

Mouse Experiments

Control of infections of Myco. tuberculosis (bovine strain) with isoniazid.—Two groups, each of 8 mice, were inoculated intracorneally with *Myco. tuberculosis* of bovine strain. One group served as a control and the other was given isoniazid in the diet. In the control animals the disease took its expected course, all but one being ultimately affected. In the treated animals, on the other hand, no lesions at all developed whilst treatment was maintained. Yet, fourteen days after cessation, characteristic lesions arose and followed a course almost identical with that in the controls. Again, most of the animals were eventually involved.

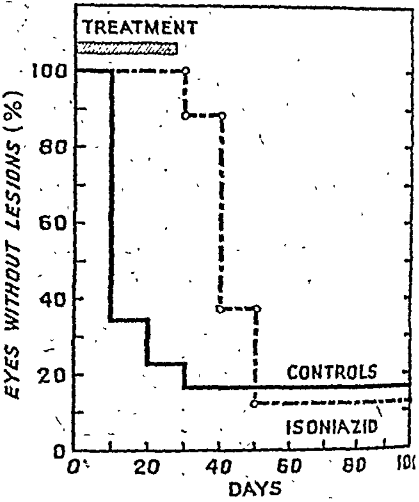

Fig. 1—The effect of isoniazid in protecting mice from experimental corneal tuberculosis (bovine strain); the incidence of the disease in untreated animals is shown for comparison.

Suppression during the course of treatment and recrudescence later are clearly shown in figs. 1 and 2.

Control of infections of Myco. tuberculosis (human strain, H37Rv) with isoniazid.—Repeating the experiment under similar conditions but using a culture of a virulent human strain of organisms there occurred, as expected, the customary lesions in the control group and, once again, a delay in the appearance of lesions in the other group until after treatment had been discontinued. This is demonstrated in figs. 3 and 4.

Significantly, perhaps, the subsequent breakdown was seen in fewer of the animals than in the previous experiment and the actual lesions were more limited.

Control of infections of Myco. tuberculosis (human strain, H37Rv) in which resistance to isoniazid had been developed in vitro.—By the kindness of Prof. Robert Knox, a culture of *Myco. tuberculosis* (H37RV) was provided in

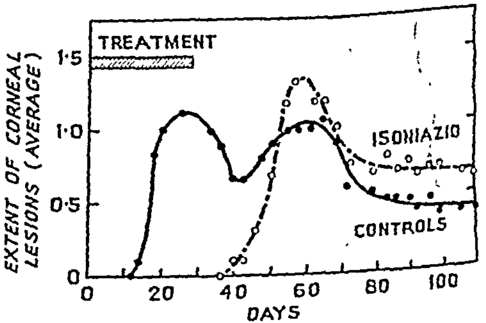

Fig. 2—Comparison of the development of experimental corneal tubercles (bovine strain) in untreated mice and in mice treated with isoniazid. The sizes of the lesions are expressed in arbitrary units, an average figure being given for each group.

which a high resistance to isoniazid had been developed in vitro by serial passage through media containing increasing concentrations of the drug (the inhibitory concentration in the test-tube was then 8–40 µg. per ml. instead of the usual 0·0128 µg. per ml.). A standardised suspension of such organisms was inoculated intracorneally into two groups, each comprising 11 mice. One group was then given isoniazid in the diet at the dosage already demonstrated as effective, while the other remained as controls. The development of lesions was then almost the same in the two groups—in time, extent, and quality (see fig. 5). Indeed, the drug had virtually no effect under these conditions—a result which has already been mentioned in a preliminary communication (Goulding et al 1952).

Control of infections of Myco. tuberculosis (bovine strain) by a combination of isoniazid and streptomycin.—Four groups, each of 15 mice, were given the usual intracorneal inoculation of *Myco. tuberculosis*, the culture being that of the bovine strain with a known sensitivity to both isoniazid and streptomycin. One group was left untreated as a control; the second received streptomycin, as described, by daily subcutaneous injections; the third was given isoniazid in the diet; and the fourth group received both drugs simultaneously. Among the controls, as expected, corneal lesions developed within two weeks of inoculation and pursued a characteristic course; all but 2 of the animals were ultimately involved. In those treated with streptomycin, the effect, as demonstrated by Rees and Robson (1950), was prolongation of the incubation period and some curtailment of the subsequent progress of the disease. With isoniazid alone the response was identical with that reported above—namely, complete suppression of the disease so long as treatment was maintained, and thereafter a relapse in which, apart from 3 animals, all exhibited lesions as seen in the controls. In the last group submitted to the combined therapy, however, not only was there complete absence of any disease during the twenty-eight days' course of treatment but, subsequently, a relapse occurred in only 4 of the animals and even then the lesions were both slow to arise and more limited in extent (see figs. 6 and 7).

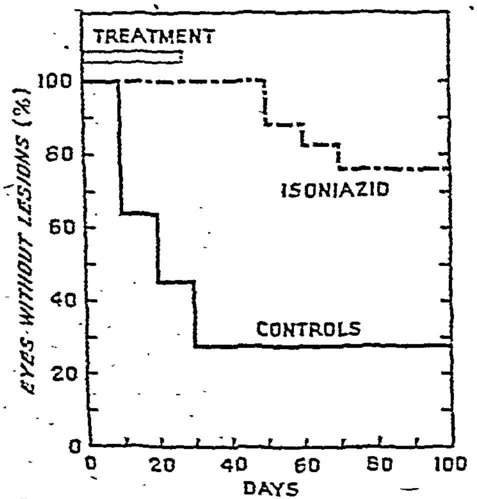

Fig. 3—The effect of isoniazid in protecting mice from experimental corneal tuberculosis (human strain H37Rv).

Control of infections of Myco. tuberculosis (bovine strain) with a combination of isoniazid and P.A.S.—In order to ascertain whether P.A.S. in combination with isoniazid would have a similar effect to streptomycin and isoniazid, yet another test was performed in mice with corneal infections of bovine *Myco. tuberculosis*. Again the controls followed a typical course. Moreover, whilst the combined drugs were administered in the doses quoted, no lesions appeared in the treated animals. Yet within three weeks of treatment being withheld the disease appeared in this group, involving, after altogether eight weeks' observation, 8 out of the 12 mice concerned. What is more, the lesions so arising advanced with that vigour generally seen in untreated animals (see figs. 8 and 9).

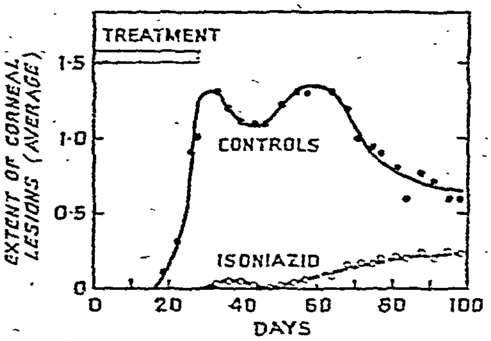

Fig. 4—Comparison of the development of experimental corneal tubercles (H37Rv) in untreated mice and in mice treated with isoniazid.

Rabbit Experiments

Acute lesions.—Of 10 adult rabbits on which bilateral corneal inoculation with *Myco. tuberculosis* (bovine strain) had been performed in accordance with the procedure outlined earlier in this paper, 2 were left untreated, while 4 were given streptomycin and 4 isoniazid in the dosages already specified. Treatment was started in each case on the day of infection. After two weeks, both the control animals bore incipient corneal lesions. These advanced steadily so that, by seventeen weeks, bilateral panophthalmitis was to be seen. The animals were accordingly sacrificed and at post-mortem examination generalised tuberculosis was found. Involvement of the lungs was gross and, indeed, in one of these rabbits radiographic evidence of pulmonary tuberculosis had been obtained five weeks previously. These findings conform to those of Gardiner et al. (1949).

By contrast, in those rabbits receiving streptomycin the onset of the lesions was delayed until almost four weeks had elapsed and, subsequently, the advance of the disease, though steady, was by no means as rapid as in the controls. Withholding treatment after eight weeks was not attended by any dramatic change.

In the rabbits given isoniazid, on the other hand, the disease was completely suppressed throughout, all corneæ remaining clear, not only during the eight weeks of treatment but even afterwards as well. The total period of observation extended over eighteen weeks. (One animal in this group was found dead a week after the experiment began. At necropsy the lungs were collapsed and hæmorrhagic, and there was some sign of hæmorrhagic colitis.)

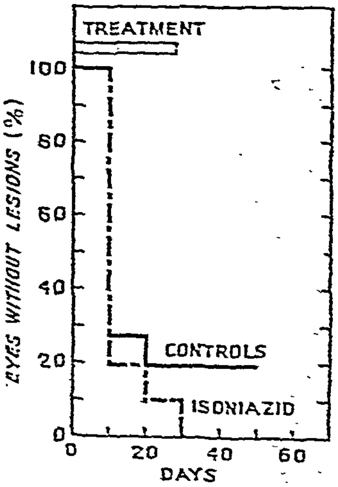

Fig. 5—The effect of using an isoniazid-resistant strain of *Myco. tuberculosis* H37Rv for inoculation of mice: the incidence of experimental corneal tuberculosis was virtually the same in both treated and untreated groups.

The distinct difference in the progress of the infection in the three groups is shown graphically in fig. 10.

Established lesions.—16 rabbits, with established corneal lesions of moderate severity from inoculation with *Myco. tuberculosis* (bovine strain) six weeks previously, were divided into three comparable groups, one being

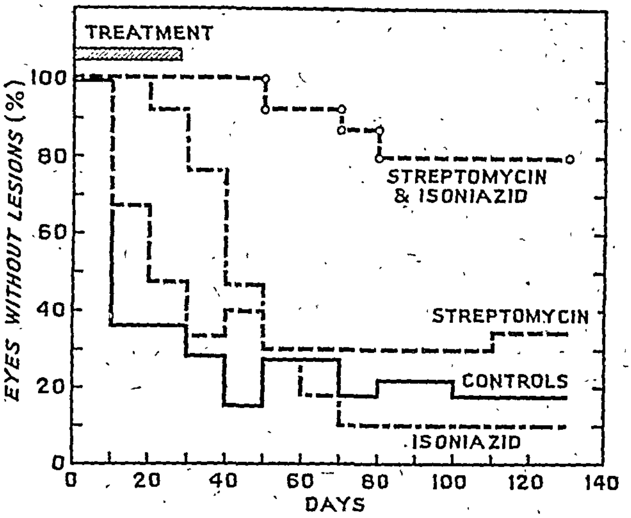

Fig. 6—Comparison of the effects of isoniazid, streptomycin, and a combination of the two in protecting mice from experimental corneal tuberculosis.

treated with streptomycin, the second with isoniazid, and the third with the two drugs together. Almost at once the lesions began to resolve and, after eight weeks of therapy, very little active disease could be seen on inspection. The corneæ were by no means clear, of course, for residual scarring remained prominent. Treatment was therefore stopped and in none of the animals was there any recrudescence in consequence. Moreover, the radiographs of the chests of these rabbits remained apparently clear.

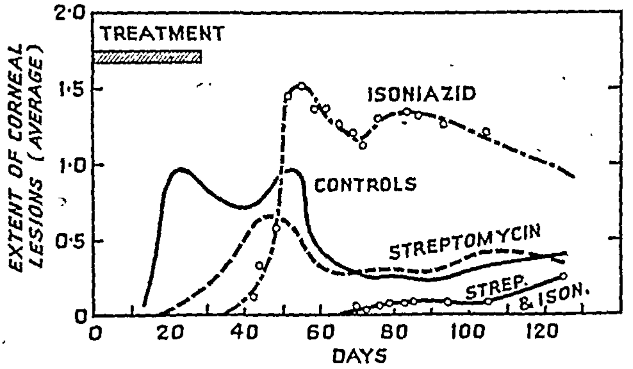

Fig. 7—Comparison of the effects of isoniazid, streptomycin, and a combination of the two on the development of experimental corneal tubercles.

Between the three methods of treatment no significant difference in response could be discerned at any stage (see fig. 11).

DISCUSSION

From these results it appears that, in mice, isoniazid by mouth in doses of the order of 12 mg. per kg. body-weight controls experimentally induced corneal tuberculosis, at least so long as treatment is continued. Once treatment ceases, however, the infection is no longer restrained. The breakdown which ensues in the corneæ is more pronounced with the bovine than with the human strain of *Myco. tuberculosis*—a distinction that is in line with their relative sensitivities to isoniazid in vitro. Such behaviour suggests that this drug is essentially bacteriostatic rather than bactericidal. Furthermore, under the conditions of these experiments, its efficacy, at least during the period of administration, is greater than that of streptomycin, though the eventual restraint imposed on the infection may be rather less. In fact, the pattern of reactions with isoniazid tends to follow that with the thiosemicarbazones tested by the same technique (Rees and Robson 1951).

The fact that resistant strains do exist is once again of sinister import, for it is clear that against these isoniazid can have little success either in vitro or in vivo. Attention has been drawn to this aspect repeatedly since isoniazid was introduced as a chemotherapeutic agent. What then becomes most important in this context is the rapidity and frequency with which such organisms may arise in clinical practice. In the report of the Medical Research Council (1952) trial it is stated that, among a sample of isoniazid-treated patients, " after one month some 10% were resistant; after two months 50%; after three months 70%." Furthermore, " those who developed drug resistance fared, as a group, less well than the others " in the matter of clinical improvement. Again, in the trial by Joiner et al. (1952) those patients receiving isoniazid alone, after benefiting almost dramatically at the start, deteriorated after eight to ten weeks; and this regression, too, was associated with the emergence of isoniazid resistance.

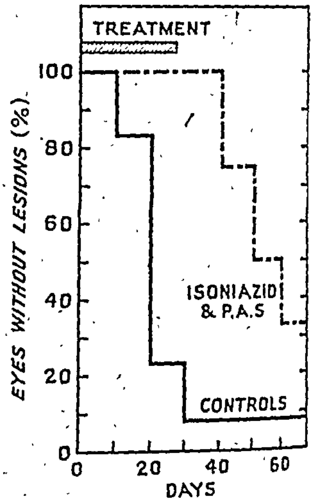

Fig. 8—The effect of isoniazid and P.A.S. in protecting mice from experimental corneal tuberculosis (bovine strain).

Data furnished by Knox et al. (1952) on the stability of the sensitivity end-point for human tubercle organisms grown in media containing isoniazid together with streptomycin or P.A.S. " suggest " that, in such circumstances, the development of resistance may be delayed. Moreover, a leading article in THE LANCET (1952) cited experiments in which a combination of streptomycin with isoniazid had delayed or averted bacterial resistance to both drugs in vitro. The suggestion was then made that " the effect of this combination in vivo should be investigated as quickly as possible," especially as large numbers of patients are already being subjected to such combined therapy. The way in which experimental corneal infections have reacted to combinations of isoniazid with other accepted antituberculous drugs may therefore be specially informative. With a streptomycin-P.A.S. régime there was complete inhibition of corneal tuberculosis in mice during the twenty-eight days of treatment; but within another twelve days all but 3 of 10 animals bore typical lesions (Rees and Robson 1951). When thiosemicarbazone (0·085% in the diet) was given along with streptomycin, the animals were not merely protected

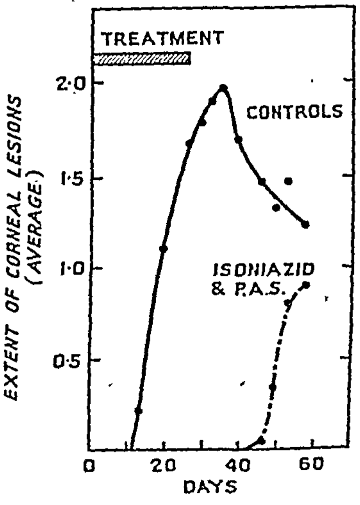

Fig. 9—Comparison of the development of experimental corneal tubercles (H37Rv) in untreated mice and in mice treated with isoniazid and P.A.S.

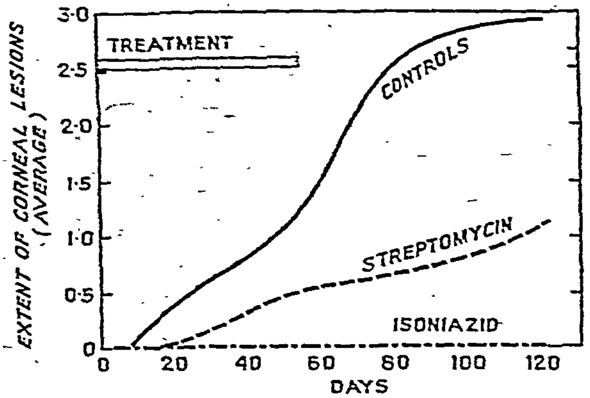

Fig. 10—Comparison of the development of corneal tubercles (bovine strain) in untreated rabbits and in rabbits treated with streptomycin and with isoniazid.

for the twenty-eight days when the two drugs were exhibited, but later, only 3 out of the 10 developed lesions during 128 days' observation. In the present series isoniazid and streptomycin gave results that were somewhat better than those with streptomycin and P.A.S., and more akin to those with streptomycin and thiosemicarbazone. Against this, isoniazid and P.A.S. together proved hardly more effective than the former drug alone.

If this technique does in fact afford some indication of the manner in which the various combinations may behave in the treatment of tuberculous patients, then the use of isoniazid in conjunction with streptomycin should be most promising—a possibility which has been at least provisionally confirmed by the results in the clinical trial now described by Joiner et al. (1952) and also the interim remarks in the report of the Medical Research Council (1952). Whether a similar combination of isoniazid and P.A.S. would prove as satisfactory in practice is, on the showing of our laboratory experiments, somewhat unlikely.

Finally, in rabbits, isoniazid showed itself more strongly antituberculous than streptomycin when used in the "umbrella" type of experiment; perhaps significantly, it so ablated the disease that there was no recrudescence after the drug was withdrawn. In this instance, therefore, it may well have behaved as a bactericide and not just as a bacteriostatic agent as on other occasions. This striking species difference between the rabbit and the mouse is difficult to explain. Normally, with corneal tuberculosis, the mouse exhibits the higher natural resistance. Yet, under the influence of isoniazid the rabbits in these experiments were completely protected. Perhaps the answer lies in the effect of temperature, to which Knox et al. (1952) have drawn particular attention. Though, as yet, corneal temperatures in the two species have not been accurately determined, nevertheless their body-temperatures, recorded rectally, show a striking difference: the average figure in the mouse is 34·3°C, and in the rabbit 38·3°C. It is interesting at this stage to speculate whether the startling responses to isoniazid by pyrexial patients can be attributed to an enhanced action of the drug where the higher temperature prevails.

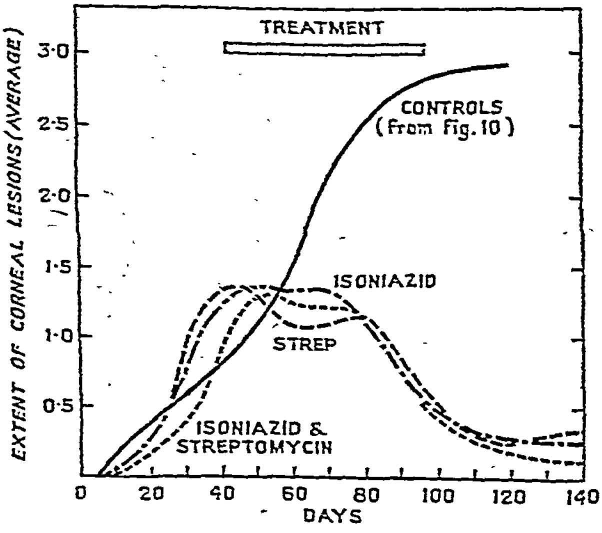

Fig. 11—The response of established corneal lesions to streptomycin, isoniazid, and a combination of the two. The control curve has been taken from fig. 10.

Against established lesions isoniazid alone by injection seemed just as potent as streptomycin or a combination of these two drugs. The prompt, uniform, and persistent response to all three modes of treatment in this experiment is in fact, surprising. That it was no more than a spontaneous regression might have been accepted had not previous and contemporary experience with controls shown that, in rabbits, experimentally induced tuberculosis of the cornea proceeds along a relentless course, so that in the end the animal is systemically afflicted.

SUMMARY

Methods are described for inducing experimental corneal tuberculosis in mice and rabbits and an account is given of the normal course of the disease in the two species.

The way in which such disease is modified by treatment reflects the antituberculous properties of the drugs employed, there being a parallel in this respect between experimental findings and clinical experience.

In mice, isoniazid alone had a suppressive effect on the tuberculous infection only while it was administered. Combined with P.A.S. it was very little more effective. When, however, the isoniazid was given along with streptomycin, the control of the disease, though not quite complete, was much more distinct.

In rabbits, isoniazid alone had a greater suppressive action than streptomycin. The difference between the two species is discussed and a possible explanation offered.

In vivo studies with isoniazid-resistant organisms are also reported.

We are grateful to the W. H. Ross Foundation (Scotland) for the Prevention of Blindness for further help in this research: to Mr. D. E. Seymour, of Herts Pharmaceuticals Ltd., for the supply of isoniazid used in these investigations; to Mr. R. W. Stanford, M.A., and Dr. John Vance, of the physics department, Guy's Hospital Medical School, who generously collaborated in the radiography of the rabbits; to Mr. P. A. Gardiner, who kindly examined the eyes in some of the rabbit experiments; and to Mr. P. Redgrave, who helped in the preparation of the figures reproduced in this article.

THE first reports about isoniazid and related substances (Fox 1951, Grunberg and Schnitzer 1952, Robitzek et al. 1952) made it clear that, whatever might be the final judgment on the value of these drugs in the treatment of tuberculosis, their highly effective and remarkably specific action on the tubercle bacillus demanded immediate study. Investigations of their in-vitro action were started at once in this laboratory, and this paper gives an outline of the experimental results obtained. Some of these merely confirm work already published, but we wish to emphasise a number of other observations which do not seem to have been recorded so far.

MATERIALS AND METHODS

Media.—For these investigations the fluid medium used was that described by Dubos and Middlebrook (1947) and was supplied by the Southern Group Laboratory, Lewisham. The basic medium containing 'Tween 80' was supplied in 100 ml. amounts, and 5% bovine albumin in 10 ml. amounts. Bovine albumin from several bottles was pooled and resterilised by filtration through a Seitz E.K. filter. For use, 4 ml. of this was added to each 100 ml. of Dubos base. Tube titrations were carried out in racks of 6 × $^5/_8$ in. tubes plugged with cotton-wool and containing 4 ml. of the complete Dubos medium. Serial dilutions of the drugs (tenfold, fivefold, or doubling) were made in these tubes. For experiments that would last several weeks, the medium was stored in screw-capped containers to prevent evaporation.

Cultures.—Cultures of the H37RV strain of the human tubercle bacillus were grown at 37°C, usually for ten days, in screw-capped bottles containing 10 ml. of Dubos medium. One drop from such a culture was added from a Pasteur pipette to each tube of [illegible] um and to a control tube containing [illegible]

Stock solutions of isoniazid and streptomycin.—These drugs were made up in distilled water in a concentration of 1000 µg. per ml. The isoniazid solution was Seitz-filtered, but the streptomycin solution was made up and dispensed under sterile conditions; the two solutions were kept in 10 ml. amounts in screw-capped universal containers at 4°C. The preparation of isoniazid used in the bulk of this work was 'Pycazide,' supplied by Herts Pharmaceuticals Ltd., who report that it is 99·63% pure according to the method Haugas and Mitchell (1952).

EXPERIMENTAL RESULTS

Measurement of In-vitro Activity of Isoniazid

Specificity of action.—Table I shows the effect of isoniazid in liquid media on human and bovine tubercle bacilli, other mycobacteria, and a number of other common micro-organisms. These results confirm the American observation that isoniazid has a highly potent and specific action on mycobacteria and especially on *Mycobacterium tuberculosis* (Pansy et al. 1952). A number of related substances have been tested for their action in vitro against mycobacteria, and they will be dealt with in a later paper.

Length of incubation.—In measuring the action of a drug on a slow-growing organism like *Myco. tuberculosis* obvious difficulties arise from the long incubation necessary before results can be read. Table II shows that at 37°C in Dubos liquid medium the end-point—i.e., the apparent sensitivity of *Myco. tuberculosis* to isoniazid—depended on the period of incubation. After incubation for from five to seven days (when growth could first be reliably recorded) the end-point was 0·01 to 0·002 µg. per ml. After longer periods of incubation the end-point progressively shifted until, after thirty-four days' incubation, growth occurred in the tube originally containing 1·6 µg. per ml. With streptomycin, on the other hand, the end-point was much more stable, and there was nothing like the same shift after prolonged incubation (see table II).

TABLE I—SENSITIVITY OF VARIOUS MICRO-ORGANISMS TO ISONIAZID

	4	0	0	0	0	0	0	0	++	++	++	++

This shift in the end-point with isoniazid has been found consistently with cultures of *Myco. tuberculosis* whenever it has been looked for by prolonging the period of incubation. It has occurred not only with H37RV but also with strains freshly isolated from patients. In performing routine sensitivity tests on such strains it is therefore clearly necessary to use standard conditions of incubation, and we have found it most convenient in practice to read our results after an incubation period of fourteen days.

Inoculum size.—We have not investigated the effect of this very closely, but it appears that the sensitivity of *Myco. tuberculosis* to isoniazid is more dependent on inoculum size than is its sensitivity to streptomycin. In one experiment a seven-day-old culture of H37RV was used, both undiluted and diluted 1 in 10 with Dubos medium, to inoculate two rows of tubes containing fivefold dilutions of isoniazid. After fourteen days' incubation at 37°C the dilute inoculum appeared to be 25 times more sensitive than the heavy inoculum. When the same cultures were tested with streptomycin, no such difference was observed between the two inocula.

Temperature of incubation.—The sensitivity to isoniazid was tested in water baths at 35°, 37°, and 40°C, and in the incubator at 37°C. In the incubator and in the water bath at 37°C the sensitivity of *Myco. tuberculosis* was found, as before, to lie between 0·01 and 0·002 *µg.* per ml. At 35°C, however, the organisms seemed to be more sensitive, and after fourteen days' incubation growth was inhibited by as little as 0·0005 µg. per ml. At 40°C the sensitivity after fourteen days' incubation was the same as at 37°C—i.e., growth was inhibited in 0·01 µg. per ml. On further incubation the shift in the end-point described above took place at 35°C and at 37°C, *but not at 40°C* (see table III).

Effect of albumin.—It is known that the activity of many substances against *Myco. tuberculosis* can be affected by the presence or absence of albumin (Youmans and Youmans 1948). Steenken and Wolinsky (1952) found that the addition of serum somewhat increased the sensitivity of cultures of *Myco. tuberculosis* H37RV to isoniazid. In our experiments using fivefold dilutions, we have usually found no significant difference in sensitivity with or without albumin. This is in marked contrast to our results with *p*-aminosalicylic acid (P.A.S.).

Effect of Streptomycin and P.A.S. on Sensitivity to Isoniazid

Streptomycin.—In a number of experiments various combinations of isoniazid and streptomycin were tested for their effect on the growth of H37RV. It was found that the shift in the end-point which was observed with isoniazid alone did not occur to anything like the same extent in the presence of concentrations of streptomycin which by themselves were not inhibitory. Part of one such experiment is illustrated in table IV.

P.A.S.—In the absence of albumin, P.A.S. strongly inhibited the growth of *Myco. tuberculosis,* either alone or in the presence of isoniazid; but, in the presence of albumin, P.A.S. alone was relatively inefficient, for it failed to suppress growth completely even in a concentration as high as 200 µg. per ml. and it gave no sharp end-point. It was interesting, therefore, to find that, in the presence of albumin, as little as 0·32 µg. per ml. of P.A.S. prevented, over a period of five weeks, the shift in the end-point to isoniazid which occurred in the same medium containing isoniazid alone (see table V).

Inactivation of Isoniazid in Uninoculated Media

We have found that in aqueous solution isoniazid withstands autoclaving at a pressure of 10 lb. per sq. in. for 10 minutes without apparent loss of activity (see table VI).

The stability of isoniazid in Dubos medium was studied by incubating solutions containing 4 µg. per ml. of isoniazid in distilled water and in Dubos medium under sterile conditions at 37°C for four weeks. At the start of this experiment and at the end of each week a sample of each isoniazid solution was tested for its drug content. Doubling dilutions in fresh Dubos medium were made, inoculated with a ten-day-old culture of H37RV, and incubated at 37° C for seven days. The highest dilution of the drug in which growth was inhibited was then recorded. Table VI shows that in distilled water the highest dilution producing inhibition of the test organism remained constant, even though the drug had been incubated for varying periods before the assay. In Dubos medium, on the other hand, the inhibitory dilution altered with each subsequent assay. As the test organism used for each weekly assay was of known and

4	0	0	+ +	+ +	+ +	+ +	+ +
5	0	+ +	+ +	+ +	+ +	+ +	+ +

In the P.A.S. control, some inhibition of growth occurred in 40 µg. per ml. (see text).

constant sensitivity, any apparent loss of sensitivity of that organism each week was clearly due to progressive decay in the activity of the drug resulting from previous incubation in the uninoculated medium. In table VI the drug content at the end of the first assay is given as 100%, but it is clear that even during the period of this and later assays inactivation of the drug must take place.

Further experiments are being done to determine the constituents responsible for this inactivation of the drug in uninoculated media. The following facts can be mentioned at this stage:

(1) Inactivation in uninoculated media increased as the temperature was raised from 32° to 42°C (see table VII).

(2) The inactivation of the drug in uninoculated media was not prevented by the addition of streptomycin.

Development of Resistance to Isoniazid in H37Rv

The experiments that have been described show that inactivation of the drug undoubtedly does occur in the absence of any organisms. Although this accounts for part of the shift in the end-point on prolonged incubation of inoculated media, it does not account for all of it. When this shift in the end-point was first noticed, it was thought to be due entirely to the presence in the bacterial population of large numbers of isoniazid-resistant strains which were being selected in the higher concentrations of the drug. An attempt was made to breed out these isoniazid-resistant strains to test: (1) the ease with which they could be produced; (2) their permanence; and (3) their resistance to streptomycin.

Production of resistant strains.—As described in a preliminary communication (Goulding, King, Knox, and Robson 1952), a culture of the H37RV strain was inoculated into a series of tubes of Dubos liquid medium, containing falling dilutions of isoniazid. During the first two weeks of incubation, growth was inhibited by a level of 0·01 µg. per ml., but after twenty-five days there was profuse growth in the tube which had contained initially 1·6 µg. per ml. From this tube one drop of culture was inoculated into a fresh set of drug dilutions in Dubos medium. In this series, the organisms grew within a week in dilutions up to 0·32 µg. per ml. and then to 1·6 µg. per ml. When further subculture was made from this tube into a fresh set of dilutions, growth was rapid in concentrations of isoniazid as high as 25 µg. per ml. Finally, on subculture from this tube after only ten days' incubation in fresh Dubos medium containing isoniazid, good growth occurred after only seven days' incubation in 62·5 µg. per ml. of the drug. The organisms therefore were now about 6000 times more resistant than in the original culture. This strain was subcultured into drug-free medium and retested for its sensitivity to isoniazid; this was found to lie between 8 and 40 µg. per ml. In similar experiments we obtained, from the original culture of H37RV, cultures which grew in 31·25 µg. per ml., but which failed to grow in 62·5 µg. per ml. of isoniazid. On more than one occasion we have observed lysis of the growth in tubes containing these high concentrations of isoniazid, but this has appeared irregularly.

TABLE VI—DESTRUCTION OF ISONIAZID IN UNINOCULATED MEDIA AT 37°C

Weeks of incubation at 37°C before assay	Medium			
	Distilled water		Dubos medium	
	Highest dilution inhibiting growth (µg. per ml.)	Drug remaining (%)	Highest dilution inhibiting growth (µg. per ml.)	Drug remaining (%)
1	0·015	100	0·015	100
2	0·015	100	0·031	50
3	0·015	100	0·062	25
4	0·015	100	0·125	12·5

Initial concentration of isoniazid in each medium: 4 µg. per ml. (see text).

We have found it possible to isolate isoniazid-resistant strains more easily than streptomycin-resistant strains, though the degree of resistance finally obtained with streptomycin has been greater than with isoniazid. In the case of streptomycin we have been able to obtain a strain resistant to 4000 µg. per ml., whereas the highest degree of resistance that we have so far obtained with isoniazid has been of the order of 62·5–125 µg. per ml.

TABLE VII—DESTRUCTION OF ISONIAZID AT DIFFERENT TEMPERATURES IN UNINOCULATED MEDIUM

Weeks of incubation at each temperature before assay	Temperature of incubation					
	32°C		37°C		42°C	
	Highest dilution inhibiting growth (µg. per ml.)	Drug remaining (%)	Highest dilution inhibiting growth (µg. per ml.)	Drug remaining (%)	Highest dilution inhibiting growth (µg. per ml.)	Drug remaining (%)
1	0·031	100	0·031	100	0·031	100
2	0·031	100	0·062	50	0·250	12·5
3	0·125	25	0·250	12·5	0·5	6·2
4	0·250	12·5	0·50	6·2	2·0	1·5

Initial concentration of drug at each temperature: 4 µg. per ml. (see text).

Permanence of resistance.—The isoniazid resistant strain obtained by the method described above was subcultured into drug-free medium at regular intervals of fourteen days, and at each subculture its sensitivity was retested. After the sixth transfer, the isoniazid sensitivity was unchanged, and lay between 8 and 40 µg. per ml.

Development of Resistance to Isoniazid in Freshly Isolated Strains

We have also investigated the development of resistance to isoniazid in strains freshly isolated from patients. The development of resistance in patients has already been reported by several workers (Steenken et al. 1952, Goulding, King, Knox, and Robson 1952), and is now described briefly by Joiner et al. (1952). We have also found that sensitive strains freshly isolated from patients can be trained in vitro to become resistant in the same way as can the H37RV strain.

DISCUSSION

Our results fully confirm the American reports that soniazid has a powerful inhibitory effect on the tubercle acillus. The drug initially inhibits the growth both f the H37Rv strain of tubercle bacillus and of strains reshly isolated from patients in very low concentrations about 0·01 µg. per ml. or less). Its activity against the ubercle bacillus is of at least the same order as that of enicillin against the Oxford staphylococcus. With a nolecular weight of 137, it is initially about 8–10 times nore efficient against the tubercle bacillus than streptomycin (molecular weight 579) when compared in equivalent molecular concentrations, and 30–40 times more fficient when compared on a weight-for-weight basis.

Its low molecular weight, its ready solubility in water, ts low toxicity, and the ease with which it is absorbed by mouth are all properties highly desirable in a drug. But its most remarkable property is its specificity. So far as is known it acts almost uniquely against mycobacteria; and within the mycobacteria its efficiency is greatest against the pathogenic members, especially the human tubercle bacillus.

For these reasons, then, quite apart from the hopes that it raises of widening the limited field in the chemotherapy of tuberculosis, the drug offers intriguing problems to both clinician and microbiologist. It became obvious at once that its success in the treatment of the disease would hinge on the ease with which resistant strains developed in patients receiving the drug. It is now well known that resistant strains develop rather rapidly in laboratory cultures (Middlebrook 1952, Hobby and Lenert 1952, Knox, Maclean, and Robson 1952) and in patients (Steenken et al. 1952, Goulding et al. 1952).

In this connection the phenomenon of the shift in the end-point and the "escape" from the effects of the drug shown in vitro by cultures of *Myco. tuberculosis* would seem to be of some importance. Some shift in the end-point has been mentioned by Hobby and Lenert (1952) and Aitoff (1952); but its possible extent and importance do not seem to have been appreciated. We know that two processes may be involved in this phenomenon: (1) a steady inactivation of the drug, occurring in uninoculated media during prolonged incubation (table II); and (2) the development of resistant variants, which can be obtained without much difficulty by appropriate methods of subculture. If the first process alone were to account for the shift in the end-point we should have to suppose that the drug was bacteriostatic and not bactericidal, that the inoculated organisms lay dormant but alive until such time as the drug concentration fell below the critical level, and that the organisms which finally grew out consisted of the original inoculum of sensitive cells. On the other hand, the second process could account for the phenomenon if nearly all the cells in the original inoculum were killed and if the growth which finally occurred were due to the multiplication of a small number of highly resistant cells in the original inoculum. The truth almost certainly lies somewhere between these two extremes.

To decide whether a drug is bactericidal or bacteriostatic is not always easy (Klarmann 1950). To some extent, it is a matter of degree. An organism exposed to an inhibitory agent for long enough will die of inanition. If removed from the influence of the drug after only a short exposure the bacterial cell may recover and, in a suitable medium, start growing again; but after long exposure it may have suffered irreversible damage and so fail to multiply even in an optimal medium.

It is still too early to say much about the way in which isoniazid acts—whether its action is mainly bactericidal or bacteriostatic, with what frequency resistant variants develop, and how their development can be arrested or delayed in different conditions.

It has been stated that isoniazid in relatively high concentrations is bactericidal (Steenken and Wolinsky 1952, Middlebrook 1952). Since, however, the drug is effective against sensitive tubercle bacilli in very low concentrations there is always a risk that even in subculture sufficient drug may be carried over to exert a continued bacteriostatic effect. The difficulty of deciding how the drug acts is increased by the inactivation which we have shown to occur on incubation in Dubos media, by the fact that the only available method of estimating it in minute quantities is microbiological assay in a similar medium, and by the fact that we have not yet discovered a reliable way of inactivating the drug so as to remove organisms at will from its continual influence. These problems are now being investigated in this laboratory.

The effect of temperature is interesting. We have shown that in uninoculated medium the drug is inactivated on prolonged incubation, and that the speed of inactivation *increases* over the range of 32–42°C. On the other hand the shift in the end-point which we have described *decreases* as the temperature of incubation is raised—in inoculated media the sensitivity of *Myco. tuberculosis* remains unchanged on prolonged incubation at 40°C, in contrast to the unstable end-point which we have found at lower temperatures.

At 35°C the initial activity of the drug appears to be many times greater than at 37°C and 40°C, though on continued incubation the shift in the end-point is even greater at 35°C than at 37°C. This is interesting in view of the claim by Eseltine and Rahn (1949) to have shown that the bacteriostatic action of some drugs is greatly *increased* at low temperatures whereas bactericidal action is more effective at higher temperatures.

Something of this kind may occur with isoniazid. Our experiments suggest that at 35°–37°C the drug is predominantly bacteriostatic, but that increase in temperature profoundly modifies its action either by making it more bactericidal or by suppressing the mechanism whereby resistant organisms become selected.

We have recently discussed the effect of heat in suppressing certain adaptive processes—e.g., penicillinase formation—which may be essential for the survival or growth of the bacterial cell, and we have suggested that quite small changes of temperature may be important in vivo as well as in vitro (Knox and Collard 1952). If isoniazid is more bactericidal at temperatures above 37°C, this would help to explain why it is the toxic pyrexial patient who responds most dramatically to the drug (Robitzek et al. 1952), and perhaps why experimental tuberculosis of the cornea (Goulding and Robson 1952) is more efficiently controlled by isoniazid in the rabbit (with a body-temperature of about 38°C) than in the mouse (with a body-temperature 4° lower). The remarkable influence of temperature on the action of isoniazid on the tubercle bacillus would seem to be an interesting field for further investigation.

The remarkable effectiveness of streptomycin or P.A.S. in preventing the shift in the sensitivity of H37Rv to isoniazid suggests that the combination of either of these substances with isoniazid may prove more effective than isoniazid by itself in the treatment of tuberculosis. How subinhibitory amounts of streptomycin act with isoniazid in preventing the shift in the end-point is being investigated further. We have found that isoniazid continues to be destroyed in Dubos medium in the presence of streptomycin. Thus the combination must act either by preventing isoniazid-resistant mutants from appearing in the culture or by turning a bacteriostatic action of isoniazid into a bactericidal effect. It looks, therefore, as though the combination acts in the same kind of way as raising the temperature of incubation.

These results together with the experimental and clinical results published in accompanying papers

(Goulding and Robson 1952, Joiner et al. 1952) indicate that, whereas isoniazid is likely to be of limited value by itself, in combination with other substances it represents an outstanding advance in the chemotherapy of tuberculosis. The remarkable specificity of its action should provide a valuable clue to the metabolism of the tubercle bacillus and in the search for other compounds with similar or even greater activity to which resistance develops less readily.

SUMMARY

These studies confirm the American statement that isoniazid has a powerful and specific inhibitory effect on *Myco. tuberculosis*. In Dubos liquid medium the growth of *Myco. tuberculosis* H37RV and of many strains freshly isolated from patients was inhibited initially by as little as 0·01 µg. per ml.

The "sensitivity," must, however, be read after a standard period of incubation, such as fourteen days, since with continued incubation the end-point shifts. This is due to two processes: (1) inactivation of the drug, which occurs even in uninoculated Dubos medium at 37°C, though in distilled water the drug is stable at that temperature and withstands autoclaving; and (2) the emergence of resistant organisms.

The speed of inactivation of isoniazid in uninoculated Dubos medium varies directly with the temperature of incubation. On the other hand, the shift in the end-point in inoculated media at 35°C and at 37°C is almost completely suppressed at 40°C.

Streptomycin or P.A.S. has the same effect as increase of temperature in delaying the shift in the end-point; yet streptomycin does not prevent the inactivation of isoniazid in uninoculated Dubos medium. It seems likely that both increase of temperature and drugs such as streptomycin or P.A.S. convert a predominantly bacteriostatic action of isoniazid into a more nearly bactericidal action.

Isoniazid-resistant strains have been isolated in vitro without difficulty, though the degree of resistance is not so great as that obtained eventually with streptomycin. Isoniazid-resistant strains retained their original sensitivity to streptomycin, and vice versa. Isoniazid resistance was found to be retained after six subcultures in drug-free medium.

The Dubos medium used in these experiments was supplied by Dr. E. H. Bailey, of the Southern Group Laboratory. We are grateful to Dr. R. J. W. Rees (Medical Research Council) for the strain of H37RV used. We should like to thank Mr. D. E. Seymour, of Herts Pharmaceuticals Ltd., for the supplies of isoniazid ('Pycazide'). In a few experiments we used a sample of isoniazid ('Rimifon') kindly supplied by Messrs. Hoffman-La Roche.

TITRATION OF STRAINS OF TUBERCLE BACILLI AGAINST ISONIAZID

D. A. MITCHISON *
M.B. Camb.

LECTURER IN BACTERIOLOGY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

THE widespread use of isoniazid (isonicotinic acid hydrazide) in the chemotherapy of tuberculosis has presented various problems to the laboratory worker. The most important aspect is likely to be the estimation of the sensitivity of strains of *Mycobacterium tuberculosis* to the drug. The purpose of this paper is to describe certain conditions which may influence any test which is employed, and in particular the effect of variations in the composition and pH of the medium, the stability to heat of the drug, the influence of the size of the inoculum, and the occurrence of resistance to streptomycin or *p*-aminosalicylic acid (P.A.S.) resistance in the strains being tested.

METHODS

Strains of Myco. tuberculosis

The virulent human strain H37RV was used for most of the work. It was obtained in 1947 from the Depot of Standard Cultures of Tubercle Bacilli, Saranac Lake, U.S.A., and was maintained for two years on Proskauer and Beck's synthetic medium and, since then, on Löwenstein-Jensen medium. Several recently isolated strains of tubercle bacilli were also employed.

Media

The following media were used: (1) a modified Dubos and Davis liquid medium containing 'Tween 80' and bovine albumin (Medical Research Council 1948), referred to as Dubos medium; (2) the same medium without the addition of Tween 80; (3) Dubos oleic-acid albumin solid medium (Dubos and Middlebrook, 1947); (4) Herrold's (1931) egg agar medium; and (5) Löwenstein-Jensen medium.

Isoniazid

This was supplied as 'Nydrazid' by Messrs. E. R. Squibb & Sons, London. A stock 1% solution was sterilised by filtration through a Berkfeld candle and was stored at 4°C.

Sensitivity Tests to Streptomycin and P.A.S.

Streptomycin sensitivity was determined by the Medical Research Council (1948) technique, and P.A.S. sensitivity by a similar method in which the inoculum was ten times smaller. The results are expressed relative to those obtained with H37RV, which was usually inhibited by 0·5 or 0·25 µg. per ml. both of streptomycin and of P.A.S.

TABLE I—SENSITIVITY TO STREPTOMYCIN AND P.A.S. OF STRAINS TESTED FOR SENSITIVITY TO ISONIAZID IN DUBOS MEDIUM

Strain	Number of times less sensitive than H37RV

---

* In receipt of a grant from the Medical Research Council.

RESULTS

Sensitivity of Strains in Various Media and Effect of Duration of Incubation

Serial twofold dilutions of isoniazid were made with -ml. amounts of Dubos medium and of Dubos medium without Tween 80 in $^1/_4$-oz. screw-capped bottles. Similar dilutions in Dubos solid medium and in Herrold's medium were prepared in $^1/_2$-oz. bottles. To each bottle was added 0·02 ml. from a ten-day culture of six strains of tubercle bacilli. In addition a further five strains were tested in Dubos medium alone. The sensitivity of these strains to streptomycin and P.A.S. is shown in table I.

After ten days' incubation the strains were inhibited in Dubos medium by 0·012 or 0·025 µg. per ml. isoniazid. In Dubos medium without Tween 80 all strains were inhibited by 0·025 µg. per ml. On the solid media the highest drug concentration on which maximum growth occurred was 0·012 or 0·025 µg. per ml. although sparse growth usually occurred on the slope with the next highest concentration.

After fourteen to twenty-eight days, as incubation continued, growth began to appear in progressively higher concentrations of isoniazid up to 1·6 µg. per ml., but not in higher concentrations even after incubation for seventy days. On solid media only very scanty colonies developed on slopes containing between 0·2 and 1·6 µg. per ml. isoniazid.

TABLE II—EFFECT OF INOCULUM SIZE ON SENSITIVITY TO ISONIAZID TESTED ON LÖWENSTEIN-JENSEN MEDIUM

Dilution of inoculum suspension	Days of incubation	Concentration of isoniazid (µg. per ml.)					
		0	0·025	0·05	0·1	0·2	0·4 and over
Undiluted ..	10	+ +	+ +	+ +	0	0	0
	28	+ + +	+ + +	+ + +	+	0	0
	56	+ + +	+ + +	+ + +	+	5	0
1 : 10 ..	10	+	+	0	0	0	0
	28	+ +	+ +	+ +	0	0	0
	56	+ +	+ +	+ +	3	2	0
1 : 100 ..	10	0	0	0	0	0	0
	28	+	+	+	4	3	0
	56	+	+	+	7	3	0
1 : 1000 ..	10	0	0	0	0	0	0
	28	8	11	8	0	0	0
	56	8	11	8	0	0	0

+ + + to + = degrees of growth. The numerals under concentration indicate the numbers of colonies on the slopes. In each case the results after seventy days' incubation were identical with those at fifty-six days.

The addition of 1 µg. per ml. of either *p*-aminobenzoic acid or of nicotinamide to Dubos medium did not alter the sensitivity of H37RV to isoniazid.

Effect of Different Inoculum Sizes

Sets of bottles of Dubos medium containing twofold dilutions of isoniazid were inoculated with fivefold dilutions of an eight-day Dubos culture of H37RV. After ten days' incubation the minimal inhibitory concentration in bottles which had received 0·1 and 0·02 ml. was 0·05 µg. per ml., whereas it was 0·025 and 0·0125 µg. per ml. in those which had received 0·004 and 0·0008 ml. respectively. With further incubation, growth appeared more rapidly and in higher concentrations of the drug in bottles which had the larger inocula.

A series of slopes of Löwenstein-Jensen medium were prepared to which isoniazid had been added before a single period of about one hour's inspissation at 80°C. These were inoculated with a 3-mm. loopful of a suspension of H37RV prepared by grinding up growth from solid medium in distilled water. The suspension was of almost equal opacity to that of a ten-day Dubos culture. The results are shown in table II. Here again it will be noted that inoculum size had little effect on the inhibitory end-point.

TABLE III—EFFECT OF pH ON THE ACTIVITY OF ISONIAZID IN DUBOS MEDIUM

pH of medium	Minimal inhibitory concentration of isoniazid (µg. per ml.) after incubation for		
	9 days	14 days	21 days
5·0	0·06	0·025	0·025
5·5	0·025	0·025	0·025
6·0	0·025	0·025	0·05–0·1*
6·5	0·025	0·05	0·4–0·8*
7·0	0·025	0·05	0·1–0·4*
7·5	0·025–0·05*	0·05	0·4
8·0	0·025	0·05	0·1–0·4*

* Where two figures are given they are those obtained when the duplicate readings did not agree.

Effect of pH

The pH of batches of Dubos medium was adjusted by the addition of hydrochloric acid or sodium hydroxide so that the final pH, after addition of albumin, ranged from 5·0 to 8·0, as measured with a Muirhead pH meter. Each batch was then distributed in 3-ml. amounts and isoniazid added in a range of twofold serial dilutions. Every set of tubes was set up in duplicate. Each bottle was inoculated with 0·02 ml. of an eighteen-day Dubos culture of H37RV. The minimal inhibitory concentration of isoniazid after incubation for nine, fourteen, and twenty-one days is shown in table III. Alterations in pH clearly have little effect on activity, if one takes into account the slower growth of the strain at pH 5·0.

Heat Stability

Incubation at 37°C.—Sets of bottles containing a range of twofold serial dilutions of isoniazid in Dubos medium were prepared under identical conditions. One collection of sets was stored at 4°C and the other at 37°C. At intervals two sets of bottles were taken from each collection and inoculated with 0·02 ml. of a Dubos culture of H37RV. The minimal inhibitory concentration of isoniazid found after ten days incubation is shown in table IV. There was no evidence of destruction at 4°C; but there was a considerable loss of activity when tubes were stored at 37°C, only about 5% of the activity being present after six weeks.

Autoclaving and steaming.—Sets of tubes containing dilutions of isoniazid in Dubos medium without albumin were prepared under identical conditions. Pairs of sets were subjected to steaming for ten and thirty minutes and to autoclaving at 15 lb. per sq. in. for fifteen, thirty, and sixty minutes. A control pair of sets was untreated. Albumin and an inoculum of 0·02 ml. of a Dubos culture of H37RV were then added to all the tubes. The minimal inhibitory concentration of isoniazid found after twelve days' incubation was 0·05 µg. per ml. in each set. Growth was considerably heavier in tubes containing 0·025 µg. per ml. which had been autoclaved for thirty and sixty minutes than in those receiving the milder treatments. This suggests that there may have been a slight loss of activity after prolonged autoclaving.

TABLE IV—EFFECT OF INCUBATION AT 37°C ON THE ACTIVITY OF ISONIAZID IN DUBOS MEDIUM

DISCUSSION

The degree of sensitivity of strains of *Myco. tuberculosis* and the lack of cross-resistance to streptomycin and P.A.S. agree well with the reports of Steenken and Wolinsky (1952) and of Pansy et al. (1952). The occurrence of growth in progressively higher concentrations of the drug with increasing periods of incubation can be explained by the presence of small numbers of resistant organisms in the original inoculum, since subcultures from tubes containing 0·4–1·6 µg. per ml. yielded strains which were less sensitive to the drug. The behaviour of these resistant strains will be discussed elsewhere. Similar findings have been reported by Pansy et al. (1952), Steenken and Wolinsky (1952), and Rist et al. (1952).

The rather small effect of changes in inoculum size resembles that found for streptomycin, but is different from that found with P.A.S. where sensitivity to the drug changes distinctly with changes in the size of the inoculum. The most pronounced effect of increasing the inoculum size was to increase the speed of appearance of resistant variants in tubes containing higher concentrations of the drug.

Alterations in pH have been shown to have little effect on the activity of isoniazid. This behaviour differs from that of streptomycin, whose activity is greatly diminished in acid media, and may be important in the treatment of tuberculosis since caseous material is often acid. Loss of activity found during incubation at 37°C has also been reported by Goulding et al. (1952). It is remarkable that there is so little loss due to heating at higher temperatures for up to an hour.

From these findings a few comments can be made on techniques for determining the sensitivity of tubercle bacilli from patients under treatment with isoniazid. It seems safe to incorporate the drug in Löwenstein-Jensen medium before inspissation. The activity will not be altered appreciably either by the heating or by alterations in the pH—a difficult factor to control in egg media. Since resistant strains obtained both in vitro and in vivo have been found to be unstable on culture in media free of isoniazid (Pansy et al. 1952, and personal observation) it would be wise to test their resistance as soon as possible after isolation. However the plating-out of sputum concentrates directly on medium containing a range of concentrations of isoniazid may be inadvisable for the following reasons:

1. The period of incubation before appearance of colonies is more variable on primary culture than on subculture. If this period is prolonged there might have been an appreciable loss of activity of the drug during incubation at 37°C.
2. An inoculum containing a small number of bacilli would yield an unreliable result, and a further test from the control tube would then have to be set up. It is at present doubtful whether such a result could be compared with the results of a direct test.

For those reasons the technique outlined by the Medical Research Council (1952) is recommended in which growth from the primary culture is inoculated directly on to Löwenstein-Jensen slopes containing a range of isoniazid contractions. The results of such tests, though not necessarily reflecting the true degree of resistance of the strains, would at least allow comparison of the results between tests and would minimise any loss of resistance during subculture.

Valuable technical assistance has been given by Miss M. Monk.

THE CORRECT PHYSIOLOGICAL BASIS ON WHICH TO COMPARE INFANT AND ADULT RENAL FUNCTION

R. A. McCance
M.A., M.D., Ph.D. Camb., F.R.C.P., F.R.S.
PROFESSOR OF EXPERIMENTAL MEDICINE, UNIVERSITY OF CAMBRIDGE

E. M. Widdowson
D.Sc., Ph.D. Lond.

From the Medical Research Council Department of Experimental Medicine, University of Cambridge

In order to compare certain aspects of renal function within the same species but in members of very different age and size, there has been a desire to find a method by which the absolute measurements may be reduced to some common basis. It was suggested by McIntosh, Möller, and van Slyke (1929) and by Holten (1931) that the comparisons should be made per unit of surface area, because in both young and old the weight of the kidney and the basal metabolic rate were proportional to this. It was found by these workers, moreover, and confirmed by others (Payne and Shukry 1934, Cullen et al. 1935) that, if surface area was used as the basis of comparison, the urea clearance of a child above the age of one or two years had the same numerical value as that of an adult. Schoental et al. (1933) found the relationship to hold for children as young as two months, and its physiological correctness and clinical value for older children have never been seriously questioned.

McCance and Young (1941) showed that, if a factor based upon surface area was used to make the comparisons between adults and very young infants, even healthy infants appeared to have lower glomerular filtration-rates and clearances of urea than adults. There were two ways of interpreting these findings. One was to suppose that the infants, although healthy, were physiologically undeveloped—i.e., that the functional capacity of the kidney of the infant had in some way lagged behind its anatomical and other physiological development. The other was to assume that surface area was not the correct basis on which to make the comparisons. McCance and Young (1941) considered various bases on which the comparisons might be made and discussed the possibilities of body-weight, kidney weight, total basal metabolic requirements, &c., and finally adopted surface area as appearing at that time the most reasonable one.

The experimental results of McCance and Young (1941) have been amply confirmed and extended (Dean and McCance 1947, Barnett et al. 1948, Rubin et al. 1949), and surface area has continued to be used as the basis of comparison (H. Smith 1951), although with some reservations (C. A. Smith 1951). This has led to the idea that there is something almost unphysiological about the healthy infant's kidney and certainly that it is an inefficient organ by adult standards. Several papers have been written, for instance, on the maturation of renal function in the first year or two of life (West et al. 1948, Rubin et al. 1949). The kidney of the newborn may be inefficient when the organ is subjected to some stress, or when some test load is applied to it (see below), and there may be differences between the tubular and glomerular adjustments of infants and adults (McCance 1950); but the following considerations suggest that the real understanding of juvenile renal function has been delayed by the selection of an incorrect basis of comparison.

EXCRETION OF UREA

If the function of the kidney is regarded as pre-eminently the regulation of the constancy of the body-fluids, three things must be borne in mind:

(1) The concentration of urea in the body-fluids varies ttle from day to day, or indeed from decade to decade.

(2) The concentration of urea in the body-fluids depends n its rate of formation and its rate of elimination.

(3) Urea is dissolved in the whole of the water in the ody, and for present purposes its concentration in this may be taken to be the same throughout.

To maintain the amount of urea in the body within ormal limits, the rate of excretion by the kidney must keep pace with the rate of formation. If in this state of dynamic quilibrium the urea formed per minute is equivalent o the amount dissolved in x ml. of the body-water, the kidney may be regarded as clearing x ml. of the body-water every minute, and it is accordingly suggested that the urea clearances should be expressed per unit of total body-water. If this be done, it becomes possible to compare the results for old and young, large and small, within any one species, by a method which is physiologically sound. Functions, moreover, on which the clearances of urea depend, such as the glomerular filtration-rate, may also very properly be compared on this basis. The excretion of water will receive special consideration later.

The accompanying table gives the average urea clearances and glomerular filtration-rates which have been found by McIntosh et al. (1929), Cullen et al. (1935), Dean and McCance (1947), Barnett et al. (1948), and Rubin et al. (1949). They are expressed in terms of the total body-water of an "average" adult as well as in terms of the adult surface area. The figures for body-water were obtained by assuming that the body of an adult weighing 70 kg. contains 60% of water—i.e., 42 litres (McCance and Widdowson 1951); that the body of a child above six months of age also contains 60% of water; and that the body of an infant under six months of age contains 69–77% of water according to its weight (Widdowson and Spray 1951). The figures obtained by Barnett et al. (1948) and Rubin et al. (1949) for healthy infants, which were well below those of adults when they were expressed per 1·73 sq. m. of surface area, are equal to those of adults when they are expressed per 42 litres of body-water. The clearances of children aged 138–356 days (Barnett et al. 1948), which were a little lower than those of adults on the basis of surface area, are higher per 42 litres of body-water, and the urea clearances of older children, which were equal to the urea clearances of adults per 1·73 sq. m. of surface area, are considerably higher than those of adults when expressed per 42 litres of body-water. This is only to be expected on physiological grounds, since the protein intake of children per kg. of body-weight, and hence per kg. of body-water, is much higher than that of adults. A comparatively small amount of this protein is required for growth in older children; and, were the clearances not higher, the concentration of urea in the body-water would normally be about 70 mg. per 100 ml. at the age of five years, which it certainly is not. It may be the level of protein metabolism in children which determines the magnitude of the glomerular filtration-rates and urea clearances. An increase or a decrease in the protein intake materially raises or lowers the glomerular filtration-rate in seals (Ladd et al. 1951), dogs (Jolliffe and Smith 1931, Shannon et al. 1932), and rats (Dicker 1948), and although the effect is much smaller in human adults it may be large in children. A high-protein diet certainly leads to renal hypertrophy in young animals (H. Smith 1951). If the renal clearances of newborn infants respond rapidly to the protein intake, the low clearances obtained by Dean and McCance (1947) (see table) may be explained, for the children used by them had been deprived of food for fifteen or sixteen hours before the tests were made.

If this physiological basis for comparing renal function of small and large individuals is adopted, some of the results and many of the conclusions about juvenile renal function will have to be re-examined. This is now being done. It goes without saying that, if the urea clearances are expressed per unit of body-water for physiological purposes, it does not prevent them from being given as a percentage of normal in clinical reports.

EXCRETION OF WATER

It is usual to study the excretion of water by administering a test dose, and to follow the response of the organism to this disturbance in the amount and composition of its body-fluids. It is clear therefore that the dose administered should be calculated in relation to the total volume of the body-water. The organism gets rid of water not only by the kidneys but also by the lungs and skin. The last two are likely to be more important in the infant than in the adult, but the figures given by Levine et al. (1938)—admittedly for older babies—show that they are relatively unimportant in the few hours following a large test dose. If, however, the organism is weighed at suitable intervals before and after the test dose, and if the volumes of water excreted by the kidney are also recorded, both the renal and extrarenal losses may be measured and distinguished.

Since the object of the experiment is really to compare the rates at which the kidney restores the composition of the body, and therefore the amount of the body-water, to normal in infancy and in adult life, the correct basis of comparison must surely be the percentage of the dose excreted, or the ml. excreted, per unit volume of total body-water. Suppose, for example, that a 70 kg. adult and a 3·6 kg. infant are given 3500 and 180 ml. of water respectively, and that they excrete respectively 3500 and 90 ml. by the kidney within the next five hours. The volumes excreted are absolute amounts, have real meaning in relation to the dose given, and are equal to 3500 and 1500 ml. if expressed per 42 litres of body-

UREA CLEARANCES AND GLOMERULAR FILTRATION-RATES

("Maximum" clearances only used)

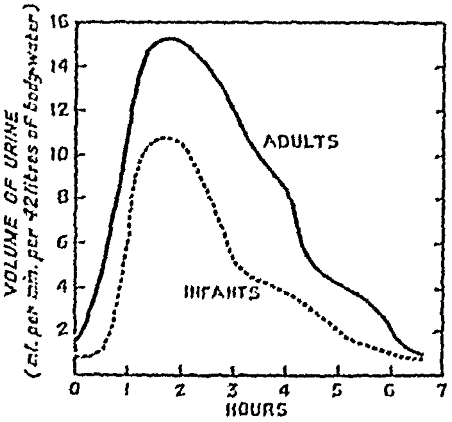
water. If, however, the figures are expressed per 1·73 sq. m. of surface area, the first remains 3500 ml. for the adult and the second becomes 630 ml. for the infant; the latter is misleading since it represents the infant as having a poorer renal function than it in fact has. McCance and Wilkinson (1947), Heller (1947, 1951), Dicker and Heller (1951), Ladd et al. (1951), and others have expressed the dosage and excretion of water per unit of body-weight. This basis is theoretically not more correct than that of surface area, but the results given by it are much nearer those based upon body-water.

Experiments recently carried out by N. J. Naylor and R. A. McCance (unpublished) suggest that the figures in the example given above are fairly near the truth for babies in the first few weeks of life. The accompanying illustration shows a comparison of the average rates of excretion of water by six infants and five adults after administering an amount equal to 6% of their body-water by mouth. The figure brings out two further points about the treatment of a large dose of water:



Minute volume of urine of infants and of adults after administration of amount of water equal to 6% of the body-water.

(1) The time relationships of the onset, peak, and course of the diuresis were very much the same at each age, and hence the absorption-rates and time relationships for the post-pituitary functions were in all probability also similar.

(2) The flow of urine subsided to its base-line in infants before the dose had been excreted, with the result that the response of the kidney came to an end while the amount and composition of the body-fluids were still abnormal. Dicker and Heller (1951) seem to have made a similar observation on guineapigs.

These findings are being further explored.

EXCRETION OF SODIUM, CHLORIDE, PHOSPHATE, AND OTHER IONS

The excretion of these substances by the kidney is a more complicated process than that of urea—at any rate less is known about it—and further experimental work is desirable before making definite suggestions about the basis on which the functions in infants and adults should be compared. A satisfactory physiological basis can only be reached if the following points are taken into consideration:

(1) The size and nature of the pool which the kidney drains.

(2) The concentration of the substance in that pool.

(3) Unless the pool is getting larger or smaller (which may happen in the metabolism of sodium), or the concentration of the substance in it is changing from day to day (which may happen in potassium or phosphorus metabolism), the amount excreted by the kidney in each twenty-four hours must equal the net quantity entering the pool.

(4) There are reasons for believing that the stability of the pool is so important physiologically that mechanisms have been developed by which the amount of a substance removed daily by the kidney may be rapidly altered to prevent variations in the amount entering the pool from materially altering its size and composition. No comparisons can be made without equating these variables or allowing for them.

COMMENT

Hitherto there has been a tendency to oversimplify the whole problem of comparing adult and juvenile renal function. The approach has been too rigid, and this has led to confusion of thought and contradictory conclusions. It may not be possible to make exact comparison on the same basis, and it is certainly not reasonable to expect to be able to do so on the basis of surface area.

Even in the so-called objective sciences any proposals involving changes in established thought or practice are likely to meet with considerable opposition (George 1936, Beveridge 1950). The suggestions now put forward certainly come into the category of those which are likely to upset current conceptions, and as such will be opposed on subjective grounds. It is hoped nevertheless that they will receive at least some objective consideration.

THE MULTILOCULAR CYSTIC TUMOUR OR ADAMANTINOMA OF THE JAW

E. D. D. DAVIS
F.R.C.S.
CONSULTING SURGEON TO CHARING CROSS HOSPITAL
From the Ferens Institute of Oto-Laryngology, Middlesex Hospital, London

THERE is considerable confusion as to the nature of adamantinoma and its treatment. The old names—"multilocular cyst," "epithelial odontome," and "ameloblastoma"—seem to have been discarded for "adamantinoma," which is admitted to be inappropriate (Lucas and Thackray 1951). "Multilocular cystic tumour" is an accurate description, but "fibrocystic disease of the jaw"—a still older name—is misleading. However, "adamantinoma" is convenient and appears to have been universally adopted for some years.

I have treated 14 cases of this tumour and have studied the reports on it published in English during the past thirty years.

A true multilocular cystic tumour or adamantinoma is not malignant, in spite of the fact that it recurs readily if it is not completely excised with its capsule intact. It begins as a solid encapsulated endosteal tumour usually in the molar region of the mandible; I have seen one only in the maxilla. This tumour grows slowly until cysts begin to form, especially just under the capsule;

ut the cysts may form in any part of the tumour. The ysts begin to expand, and then the tumour rapidly ncreases in size, spreading upwards into the ascending amus of the mandible. When the cysts burst through he alveolar plates, the tumour extends into the soft issues of the floor of the mouth or into the cheek. Very arge tumours have extended from the coronoid process nto the pterygomaxillary fossa.

Specimen no. 385 in the museum of Charing Cross Hospital ledical School is a solid encapsuled nodular tumour attached o the crown of a molar tooth. *The roots of the tooth are* underdeveloped. This tumour was enucleated from the nandible of a boy, aged 5 years, fifty-one years ago. The istological section showed it to be what was then called an pithelial odontome.

HISTOLOGY

The histology of the tumour varies, but it is an pithelial tumour with follicles lined by a layer of typical palisade-like columnar cells and containing a fine stellate reticular tissue. The palisade epithelial cells resemble the ameloblasts, and the stellate tissue is like that of the enamel organ of the developing tooth germ. There is little evidence that these tumours arise from the developing tooth germ, and similar tumours have been found in the long bones of the skeleton. Coley (1949) has collected 18 such cases. I have examined the histological sections of 10 tumours and found no connection between the surface epithelium of the gum and the tumour. The fine interstitial tissue may contain groups of epithelial cells and small cysts. The groups of epithelial cells have been mistaken for carcinoma cells, but it is more common for a basal-celled carcinoma or an adenocarcinoma to be mistaken for an adamantinoma. I have known 3 basal-celled carcinomas and 2 adenocarcinomas to be diagnosed as adamantinoma. A basal-celled carcinoma arises from the surface epithelium, and the club-like processes of large epidermal cells spread into the deeper tissues. I have never seen a malignant adamantinoma. Two or more cases of metastatic growths secondary to an adamantinoma have been recorded (Coley 1949, Waterworth and Pullar 1948), but possibly the primary tumour was not a true adamantinoma. Lucas and Thackray (1951) describe eight different histological types of adamantinoma, ranging from the primitive type to the melano-ameloblastoma. Three sections of tumours which have recurred after incomplete removal (one after scraping) show a considerable increase of the epithelial cells in the interstitial tissue compared with the first tumour removed.

DIFFERENTIAL DIAGNOSIS

Clinically these tumours resemble in some ways the simple encapsuled parotid tumour. There are four different types of parotid tumour, according to the predominance of the kind of tissue forming its structure: the fibrous tumour, which is very similar histologically to the primitive type of adamantinoma; the myxomatous; the mucous; and the epithelial. The epithelial type of tumour has in the past been called an endothelioma, or cylindroma: it is now called an adenoma and is sometimes malignant. The parotid tumour has been found anywhere in the mouth, palate, cheeks, jaws, and pharynx, and in the neck.

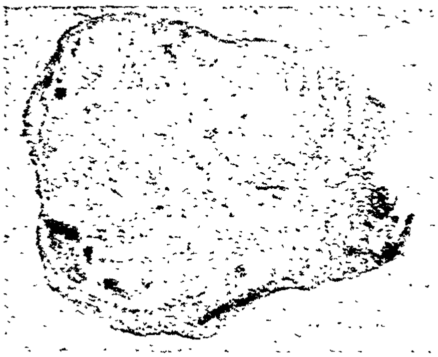

Fig. 2—Recurrence of tumour in 1951 in operation scar of 1931 (see fig. 1).

The diagnosis of adamantinoma is usually obvious—biopsy is rarely necessary, and there are good reasons for not taking a biopsy specimen from an encapsuled tumour. There is no difficulty in recognising a carcinoma or an adamantinoma during its removal. Of course a large piece of the tumour is sectioned immediately after it has been removed.

TREATMENT

Complete excision by diathermy and dissection is the most successful treatment. The coöperation of a dental surgeon is necessary because the jaw may have to be resected. Apparatus to fix the fragments of the jaw and interdental splints should be made, and septic teeth should be extracted before the operation. The tumour should be thoroughly and completely exposed and its limits defined. To achieve this, good access is necessary. Stereoscopic X-ray photographs are studied to assist in the definition of the limits of the tumour.

The choice of mouth gag is important. I prefer the Davis gag with its tongue-depressor, and it is a very satisfactory gag for an edentulous patient (Warwick James 1940). When this gag is used, the patient's head is extended over a sandbag in the position for enucleation of the tonsils. An efficient headlamp and a suction pump are essential. If the tumour is in the lower incisor region the patient is well propped up in the sitting position with the surgeon standing and looking down on the teeth. Denhard's gag is useful for a tumour in the incisor area.

Division of the lower lip in the midline does not give much better access; it causes deformity of the mouth by drooping of its angle and it is really unnecessary. Division of the upper lip for tumours of the upper alveolus gives better access without subsequent deformity. When the maximum exposure of the operation area has been obtained, a long incision of the mucoperiosteum is made down to bone at the lowest point of the cheek sulcus. The incision is made with a diathermy cutting needle from the ascending ramus to the symphysis. A similar incision is made as low down as possible on the inner or buccal surface of the mandible, and the two incisions are united well behind and well in front of the tumour to include an elliptical area of the surface mucoperiosteum, which is excised with the

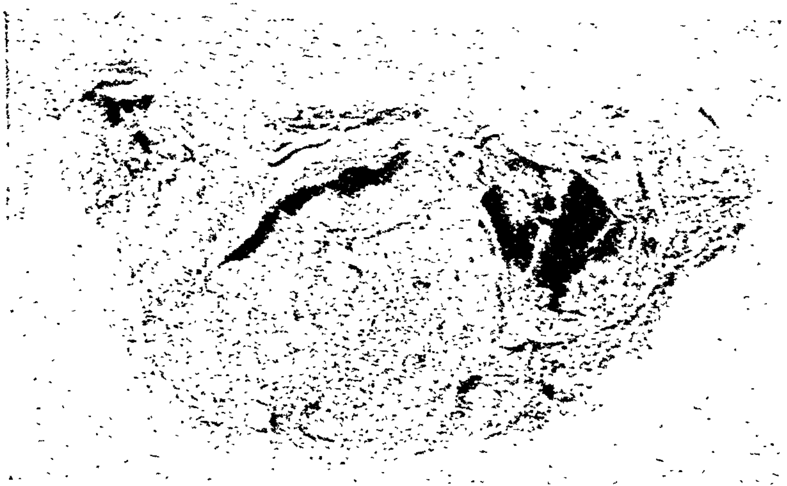

Fig. 1—Multilocular cystic tumour removed by resection of jaw in 1931

tumour. The mucoperiosteum is rasped off the bone to the lower edge of the mandible. Four or five pairs of curved artery-forceps are clipped to the edge of the mucosa and, if allowed to hang down, act as good retractors of the lip and cheek. The mucosa of the buccal surface is rasped *off the bone, and then the* thinned covering bone is removed with nibbling forceps all around the tumour and beyond its circumference and to the bottom of the bony cavity.

When the tumour is fully exposed it is dissected away with a blunt flat dissector working well outside the capsule and any of its cystic prolongations. Great care is taken to preserve the capsule intact.

I have completely excised 8 of these tumours in this way. At the end of five years there was no recurrence; in 2 cases there was still no recurrence after sixteen and twenty years. If it is found, when the tumour has been removed, that it has an inaccessible prolongation upwards into the ramus or any other part of the mandible, the jaw can be resected with a Gigli saw through a large external flap incision. Scraping and trying to enucleate the tumour with a sharp spoon is useless—recurrence is almost certain, and then it is more difficult to define the tumour and to excise it completely. If a small prolongation is left, or even if the capsule is ruptured, recurrence is probable. I am opposed to the set operation of resection of the jaw without first defining the limits of the tumour. If the tumour recurs after a complete excision, then a resection of the jaw may be necessary. In a few advanced cases the diagnosis has been too late and resection is the only possible operation which will achieve a complete removal of the tumour. The earlier the diagnosis the better the prospect of a complete removal. I have seen 2 cases of recurrence of the tumour twenty-one years and ten years after resection of the mandible.

In a case illustrated in the Middlesex Hospital museum an alleged dentigerous cyst containing two inverted teeth was incised and scraped in 1910. In 1924 a tumour recurred which gradually increased in size until in 1928 a solid tumour with a cyst was excised. In 1931 there was a recurrence, for which the jaw was resected (fig. 1). In 1951 an encapsuled globular tumour recurred (fig. 2), which was dissected out of the scar tissue by Mr. Douglas Ranger.

In my experience deep X-ray therapy has been unsatisfactory and disappointing. It is difficult to imagine that an embedded cystic encapsuled tumour should disappear with radiotherapy. The most that happens is that the cyst wall becomes fibrosed and thickened, and excision of the tumour is made more difficult. Necrosis of the bone, osteomyelitis, and burning of the mucosa and skin have occurred without any benefit, but with considerable misery to the patient. X-ray photographs after radiotherapy may show improvement by fibrosis in the superficial part of the tumour, but the more inaccessible deep portion remains. Recurrence of the growth is inevitable within a year or so.

Radiotherapy has been recommended in the extensive inoperable tumour which has burst through the bone into the soft tissues and inaccessible areas—for example, in an old man who has had a coronary thrombosis or is in bad physical condition. I prefer to treat this type of case by draining the cysts through large openings.

I am indebted to the Ferens Institute of Otolaryngology and to Dr. A. C. Thackray, of the Bland-Sutton Institute of Pathology, Middlesex Hospital, for the opportunity of studying specimens and sections; also to Mr. B. W. Fickling and Mr. Rainsford Mowlem.

PLASMA-ESTERASE AND PLASMA-LIPASE LEVELS IN NUTRITIONAL ŒDEMA SYNDROME (KWASHIORKOR)

P. R. SRINIVASAN
M.Sc. Benares

V. N. PATWARDHAN
M.Sc. Bombay, Ph.D. Lond.

From the Nutrition Research Laboratories of the Indian Council of Medical Research, Coonoor, South India

THE effect of malnutrition on the production of enzymes by tissues has been receiving increasing attention in recent years.

Hutchinson, McCance, and Widdowson (1951) found the serum-cholinesterase level below normal in undernourished Germans in Wuppertal. According to them an insufficiency of calories was responsible for decreasing the pseudo, and to a lesser extent of the true, cholinesterase activity; the deficiency of neither protein, nor fat, nor carbohydrate, nor any of the major dietary constituents was considered to be specifically involved.

Hutchinson (1951) observed that undernutrition did not alter the levels of true cholinesterase, phosphatase, catalase, or glyoxalase in red blood-cells, although there was some indication of a slight increase in the level of carbonic anhydrase. However, in dogs and rats, even in severe malnutrition, the serum-pseudocholinesterase level was not lowered.

Veghelyi (1948) observed by duodenal intubation a diminution in the output of pancreatic enzymes in malnourished children in Vienna. The first enzyme to diminish and then to disappear was the lipase, and the last the amylase. He also observed that the blood-lipase and blood-amylase levels were considerably lowered in protein-deficiency states. Dietary treatment with milk powder brought about clinical improvement and a recovery of the enzyme activity.

Thompson and Trowell (1952), who compared by duodenal intubation the pancreatic enzyme activity in 24 African normal children and 59 cases of "a type of kwashiorkor," found the activity of pancreatic amylase and lipase in the kwashiorkor group much lower than in the normal children. In most cases the enzyme activity returned to normal after successful treatment with whole milk, skim-milk, or milk protein alone.

A syndrome similar to, and probably identical with, kwashiorkor has been under investigation at Coonoor for the last four years (Ramalingaswami et al. 1948, Gopalan and Patwardhan 1951). So far, 80 cases have been investigated and treated. In a fairly large number of these the plasma-lipase and plasma-esterase levels were estimated.

We present here the results of our observations in 17 normal children and in 33 with nutritional œdema resembling kwashiorkor.

METHODS

Plasma-esterase was estimated by the method of Cherry and Crandall (1931).

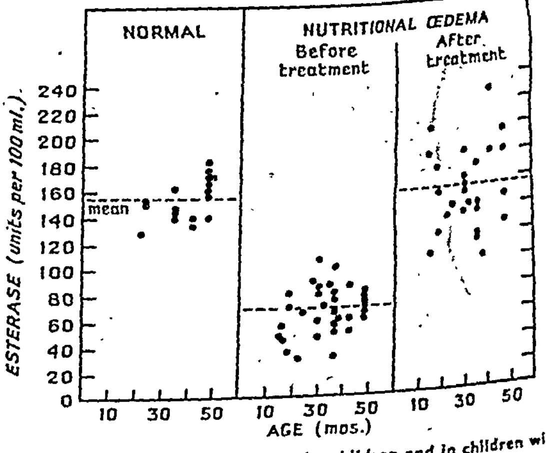

Fig. 1—Plasma-esterase levels in healthy children and in children with nutritional œdema.

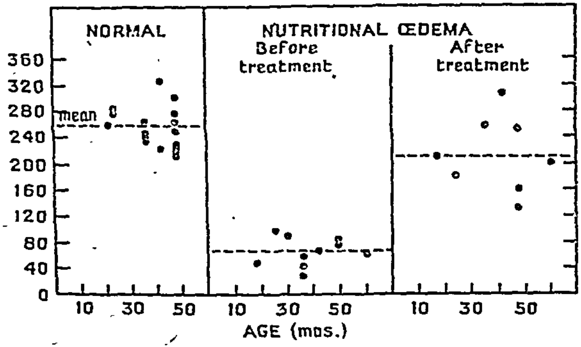
TABLE I—PLASMA-ESTERASE AND PLASMA-LIPASE LEVELS IN KWASHIORKOR AND IN HEALTHY CHILDREN

	Age range	Plasma-enzyme level (units per 100 ml.)							
		Before treatment				After treatment			
		No. of cases	Range	Average	Standard error	No. of cases	Range	Average	Standard error
rase :									
n kwashiorkor ..	From 1 yr. 3 mos. to 4 yr.	33	30–105	66·7	± 3·25	27	100–230	154	± 6·64
n healthy children ..	From 1 yr. 10 mos. to 4 yr.	17	130–180	153·5	± 3·61	—	—	—	—
ase :									
n kwashiorkor ..	From 1 yr. 6 mos. to 5 yr.	10	30–100	67·0	± 6·80	8	130–305	211	± 20·10
n healthy children ..	From 1 yr. 10 mos. to 4 yr.	17	215–325	258·5	± 7·30	—	—	—	—

Plasma-lipase in the earlier part of the investigations s estimated by the method of Goldstein et al. (1948); t it soon became apparent that, owing to its non-cificity, the method could not give correct values for ase. Certain modifications were introduced, the most portant being the addition of sodium tauroglycocholate the reaction mixture in a final concentration of × $10^{-3}M$ containing tributyrin and plasma. In the esence of tauroglycocholate at the given concentration e esterase activity of plasma towards tributyrin is mpletely inhibited; hence the estimation gives a asure of lipolytic activity alone. The procedure and nterpretation of results obtained by this method are escribed elsewhere by Srinivasan and Patwardhan (1952).



g. 2—Plasma-lipase levels in healthy children and in children with nutritional œdema.

MATERIAL

The patients investigated were children, aged 15–48 onths, of stunted growth, with œdema and diarrhœa. n addition, enlarged liver, dermatosis, and depigmentaion of hair—the other features of typical kwashiorkor—ere present singly or together in a fair number of cases. he diarrhœa was non-infective and the œdema not of ardiac or of renal origin. Plasma-esterase and plasmaipase were estimated in blood obtained on admission nd on discharge. All the cases were treated with econstituted skim-milk, the quantities of which were radually increased according to the tolerance of the atient. In the later stages the skim-milk was supplemented by the hospital diet. On discharge, when a second ample of blood was taken for enzyme studies, the œdema had completely disappeared, the liver, if previously enlarged, had receded, and dermatosis had esponded.

RESULTS

The results of observations of enzyme activity are summarised in table I and figs. 1 and 2. The plasmaesterase and plasma-lipase levels, by age-groups before nd after treatment, behave (figs. 1 and 2) very much ike those of the pancreatic enzymes (amylase, lipase, and trypsin) as described by Thompson and Trowell (1952).

Plasma-esterase levels in 33 cases on admission were 30–105 units per 100 ml., with a mean of 66·7 units. After treatment the observations were repeated in 27 cases only, the levels being 100–230 units per 100 ml., with a mean of 153·8 units. Statistically this difference is significant ($P < 0.001$). The range and the average levels in a comparable age-group of normal and apparently healthy children are also given in table I, from which it is clear that, when treatment produced distinct clinical improvement, the plasma-esterase level returned to *normal.*

Plasma-lipase levels were estimated according to our modification of the method of Goldstein et al. (1948) in only ten cases before treatment and in only eight cases after treatment. From table I it is clear that the changes in plasma-lipase levels are similar to those in plasma-esterase levels.

DISCUSSION

Plasma-esterase

Whipple (1913) suggested that the plasma-esterase level could be used to measure liver function. Holmes and Trowell (1948) reported the failure of liver-cells from biopsy specimens to store glycogen in the presence of liberal amounts of glucose in their cases of kwashiorkor. Waterlow (1950) found a low cholinesterase activity in liver-biopsy specimens in his two cases with fatty liver. These observations make it probable that in kwashiorkor, which seems to be invariably associated with structural and functional damage to the liver, the plasma-esterase level is below normal.

In table II an attempt has been made to compare the degree of fatty infiltration of the liver with the plasma-esterase level in cases where liver structure in biopsy material could be examined. Although it may be too early to draw any conclusion, it does seem possible that some relation may exist between the degree of liver damage and the activity of plasma-esterase. At present not enough biopsy material has been collected before and after treatment to allow comparison in greater detail between the increase of plasma-enzyme activity and alterations in liver structure.

The plasma-esterase levels in patients before treatment show a wide divergence. On the other hand, in every case investigated a distinct rise in the plasma-esterase

TABLE II—PLASMA-ESTERASE AND FATTY INFILTRATION OF LIVER

Case no.	Esterase (units per 100 ml.)	Fatty change *
	(Before treatment)	
1	50	+ + + +
2	65	+ + +
3	60	+ + +
4	75	+ + +
5	75	+ +
6	70	+ +
7	75	+ +
8	80	+ +
9	100	+

* The severity of fatty change was graded as follows:
+ Tiny sudanophil droplets in the cytoplasm of liver-cells.
+ + + + Coalescence of sudanophil droplets in adjoining liver-cells, giving the appearance of large fat cysts.
Intermediate stages were graded + + and + + +.

level was observed after treatment. The final levels after treatment compare favourably with the normal levels in a comparable group of apparently healthy children.

Plasma-lipase

This enzyme probably has its origin in the pancreas. Ordinarily a very small part of the pancreatic enzymes enters the circulating blood, and this is normally excreted in the urine. In conditions like pancreatitis, pancreatic lithiasis, and cancer of the head of the pancreas, increased amounts of amylase circulate in the blood and can be found in the urine in higher concentrations than in normal people (Peters and van Slyke 1946). In these conditions the acinar function is normal, but the secretion of the enzymes into the ducts, or their entry into the duodenum, is interfered with. It might be expected that, in conditions where the capacity of the acini to elaborate the enzymes is impaired, the levels of pancreatic enzymes in the blood would be lower than normal. Davies (1948) has described the structural changes in the pancreas in kwashiorkor, the lesions varying from minor degenerative changes to advanced fibrosis and atrophy. Diminished pancreatic function has been observed by Veghelyi (1948) and Thompson and Trowell (1952) in kwashiorkor. These observations would explain the diminished plasma-lipase activity. According to the latter workers, successful treatment improves pancreatic function, a finding which seems to fit in with the improvement of plasma-lipase levels observed by us. Estimation of plasma-lipase levels may prove to be a more convenient method of determining the state of pancreatic function in kwashiorkor than is duodenal intubation. However, further work, including the estimation of plasma-amylase and plasma-trypsin levels, must be done before this can be accepted.

The plasma-lipase and plasma-esterase levels did not reveal any correlation with total plasma-protein or with plasma-albumin or plasma-globulin. The total-protein levels in 11 cases in the present series were 3·35–5·67 g. per 100 ml., with an average value of 4·8 g., before treatment, and 5·75–7·7 g. per 100 ml., with an average value of 6·87 g., after treatment.

SUMMARY

The plasma-esterase and plasma-lipase levels have been studied in 33 children with nutritional œdema, a condition similar to and probably identical with kwashiorkor, and in 17 apparently normal children who were comparable in age and derived from the class of people in whom this condition is prevalent.

In all the children with nutritional œdema the plasma-esterase and plasma-lipase levels were well below normal.

Therapy with skim-milk restored the levels to normal.

The possible cause of the lowered levels and their relation to nutritional œdema are discussed.

We gratefully acknowledge the assistance received from the nutrition clinic and the pathology department of the Nutrition Research Laboratories in the conduct of this investigation.

Medical Societies

MANCHESTER MEDICAL SOCIETY

Heart-disease and Pregnancy

AT the first meeting of the session, on Oct. 7, Prof. J. CRIGHTON BRAMWELL was inducted as president and delivered a presidential address on Heart-disease and Pregnancy.

Professor Bramwell referred to the part a medical society might play in helping to close the gap between consultants and general practitioners, and in bringing the practitioner into closer touch with the growing-points of knowledge. He suggested that the wealth of clinical material in Manchester imposed a corresponding obligation on those working there to undertake clinical research.

Over 1600 pregnant women with organic heart-disease had been investigated in his clinic at the Manchester Royal Infirmary during the past twenty-five years. The first 350 cases had been analysed by Dr. Edith Longson and himself in 1938, and 500 of the more recent cases had been similarly analysed by Dr. Morgan Jones.

The risk of pregnancy in patients with heart-disease depended on the severity of the disease, and could usually be assessed by the patient's tolerance for exercise before pregnancy. In patients with trivial heart-disease the risk was negligible; in those whose tolerance for exercise was reduced to a greater or lesser extent the added risk was appreciable; while in those who had suffered from heart-failure the risk was prohibitive. Pregnancy was contra-indicated in patients with active rheumatic carditis and in those whose cardiac condition was deteriorating rapidly. Intercurrent infection, especially bronchial infection, and anæmia were important and preventable causes of heart-failure. The prospect of successful pregnancy must also be considered. I the more recent series, 4 out of 5 pregnancies had yielde living children; whereas in 53 patients with advance heart-disease who were seen too late for pregnancy to b terminated, or who were unwilling to have it terminate only 1 in 4 was successful. Acute pulmonary congestio in patients with mitral stenosis constituted a grav emergency which was liable to develop very suddenl and often resulted in death; if it was recognised in th first trimester, pregnancy should be terminated. Valvotomy was now a possible alternative to termination o pregnancy. In addition to the clinical evidence, X-ray screening was invaluable in the early recognition of this condition.

Auricular fibrillation did not add so greatly to th risk as most earlier workers had imagined. Unde favourable conditions it should not be regarded as a bar to pregnancy.

In patients who had never actually had heart-failure, but whose tolerance for exercise was much restricted assessment of the risk was most difficult; and factor other than the severity of the heart-disease—namely age and parity, temperament, and economic conditions—all had to be taken into consideration. The addition o an aortic lesion to mitral stenosis did not add to th risk. Opinions varied regarding the importance o cardiac enlargement, but many patients who died o acute pulmonary œdema had little cardiac enlargement

A case follow-up in the more recent series showed tha about 90% of patients who survived had no evidence cardiac deterioration as the result of pregnancy.

With regard to treatment, Professor Bramwell believe that the two most important things were: (1) never t interfere with pregnancy in a patient with heart-failu until everything possible had been done to relieve t heart-failure; and (2) to ensure adequate antenat supervision in every case. If heart-failure was recognise early it responded well to treatment. In the antenatal cardiac clinic the almoner played a most important part.

It was now known that in the last few weeks of pregnancy blood-volume and cardiac output diminished, and that the strain on the heart was correspondingly reduced. There was therefore no justification, in this respect, for anticipating normal delivery by inducing premature labour or by cæsarean section. All recent work showed that in patients with heart-failure cæsarean section carried a heavier mortality than normal delivery.

New Inventions

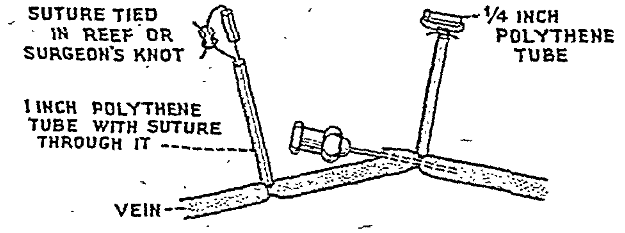
A TECHNIQUE FOR SAVING THE VEIN

FOR administering continuous intravenous fluids to children it is usual to cut down on a vein and tie it off. The method described here is designed to preserve the patency of the vein for subsequent intravenous therapy. It is based on the assumption that after a few hours' intravenous therapy little bleeding will take place, because of spasm and sometimes thrombosis of the vein.

As an alternative, it has been suggested that after a vein has been dissected out, it may simply be needled without tying; but I have found this unsatisfactory because of bleeding round the needle at the point of puncture.

The usual cutting-down apparatus is required, and also a piece of 'Polythene' tube. The polythene is cut into four lengths, two of 1 in. and two of $^1/_4$ in. The size of the polythene tubing is not important, but no. 3 is quite satisfactory.

The vein having been exposed, two catgut sutures are placed round it in the normal way. The ends of these sutures are threaded loosely through the long pieces of polythene (see figure), and artery forceps are applied to the polythene. A snick is made in the vein and the cannula is introduced. The two sutures are now drawn tight through the polythene, one being placed round the cannula and one distal to it (the artery forceps having been removed). One end of each suture is threaded through the smaller piece of polythene, and the suture is secured with a surgeon's knot. It will be seen that this is a modification of the Bowden-wire principle.



SUTURE TIED IN REEF OR SURGEON'S KNOT
1/4 INCH POLYTHENE TUBE
1 INCH POLYTHENE TUBE WITH SUTURE THROUGH IT
VEIN

When the transfusion is finished, the cannula is extracted and an attempt is made to suture the vein wall. Then the sutures are cut and removed. Even if it is impossible to suture the cut in the vein, bleeding can be easily controlled by skin sutures and a pressure bandage.

The method has been applied successfully in the treatment of infants with gastro-enteritis who have required intravenous therapy. The long saphenous vein has been used. At the conclusion of the transfusion it has always been found possible to remove all the sutures without untoward effects, and there has been no leaking from the vein during the infusion. The method was also used in giving blood to a boy with acute leukæmia who had a hæmorrhagic tendency shown by widespread ecchymoses and purpuric spots. There was slight bleeding from the vein at the conclusion, but it soon stopped when a tight bandage was applied at the site of the incision.

I have had an opportunity of using this method for a second time on the same vein. A child, aged 1, was transfused during the treatment of an ulcerating hæmangioma affecting both legs. A second transfusion was needed three months later, and I cut down on the same vein. There was no real difficulty in introducing the cannula and though the lumen of the vein seemed a little narrower the transfusion was entirely satisfactory.

This method might appeal to those who have to give repeated transfusions to the same patient over several years—e.g., in congenital hypoplastic anæmia.

Senior Pædiatric Registrar, Farnborough Hospital, Kent	R. P. ARONSON M.B. Lond., M.R.C.P.

Reviews of Books

Principles and Practice of Medicine

A Textbook for Students and Doctors. L. S. P. DAVIDSON, M.D., F.R.C.P.E., professor of medicine and clinical medicine, University of Edinburgh. Edinburgh: E. & S. Livingstone. 1952. Pp. 919. *32s. 6d.*

Professor Davidson, with the staff of the medical department and clinical units at Edinburgh, has compiled a textbook embodying the teaching of this school over the past twenty years. This volume is clearly produced and simply designed. A similar descriptive pattern is used for each disease, giving concise ætiology, pathology, clinical manifestations, diagnosis, and treatment. As would be expected from this group of teachers, the physiological background is well covered and special emphasis has been laid upon treatment: it is indeed pleasant to find this aspect so well handled. The selection of material is admirable, and the student will find enough about rare diseases to serve him for his final examinations.

The printing and production is first-class. Some readers may wish for more illustrations, but they must remember that the price is remarkably low for all this volume provides. Davidson's textbook will assuredly take its place as a real contribution to British medical teaching.

Oestrogens and Neoplasia

HAROLD BURROWS, C.B.E., PH.D. Lond., F.R.C.S., formerly *experimental pathologist, Chester Beatty Research* Institute, The Royal Cancer Hospital, London; E. S. HORNING, M.A. Oxfd, D.SC. Melb., reader in experimental pathology, University of London, at the institute. Oxford: *Blackwell Scientific Publications.* 1952. Pp. 189. *30s.*

IN addition to its main theme this volume includes an account of the chemistry of œstrogens by C. W. Shoppee and a brief summary of experimental tumour chemotherapy by W. C. J. Ross. A preliminary chapter sets out the natural sources of œstrogen from plants and animals, as well as factors controlling its supply in the body and influence in stimulating mitosis, hyperplasia, and benign and malignant growths. From observation of human and experimental conditions, the authors support the view that continuous secretion of, or exposure to, œstrogen rather than intermittent excessive output or application is the effective hormonal factor causing spontaneous or induced neoplasia. Among other special conditions cited are species and organ variation in sensitivity and response and, within the same species, differences depending on heredity and inbreeding. In the case of heritable mammary tumours of mice the effective cause is infection with the milk factor aided by œstrogen. Subsequent chapters summarise systematically knowledge of the neoplastic influence of œstrogen on its target organs. A short account of œstrogen-producing tumours is included. Numerous subheadings and cross-references help the reader to extract and to trace to source any special information required. There is a bibliography of 957 references.

Surgery of the Œsophagus

R. H. FRANKLIN, M.B., F.R.C.S., senior lecturer and surgeon, Postgraduate Medical School of London. London: Edward Arnold. 1952. Pp. 222. *42s.*

IN this work Mr. Franklin has considered the œsophagus as a whole, and he has used his experience to draw into reasonable perspective the work in this field of the ear, nose, and throat surgeon, the thoracic surgeon, and the abdominal surgeon.

He writes with authority on the operative treatment of congenital atresia, and it is interesting to note that he has now a preference for the transpleural as opposed to the extrapleural approach. In his brief but clear discussion of the technique of œsophagoscopy he emphasises its potential dangers in incautious hands. Apart from diagnosis, endoscopy plays an important part in the removal of foreign bodies, but there are some complications which require the use of open surgery. He considers the syndrome of reflux œsophagitis, resulting from a shortened œsophagus with herniation of the stomach, in the light of recent work, and illustrates the difficulties of treatment. In the description of the operative treatment of carcinoma of the cervical and thoracic œsophagus, the absence of many figures and results make it difficult to determine the appropriate technique for each case.

The illustrations are well selected. All interested in the œsophagus should read the book, for it is a valuable contribution to a subject which is rapidly developing.

Psychology, the Nurse, and the Patient

Doris M. Odlum, M.A. Oxfd, B.A. Lond., M.R.C.S., D.P.M., senior psychiatrist, Elizabeth Garrett Anderson Hospital, and consultant psychotherapist, West End Hospital for Nervous Diseases, London. London: *Nursing Mirror* Publications. 1952. Pp. 114. 7*s.* 6*d.*

This pocket-size book should be of real help to student nurses, for it covers the syllabus in psychology for the preliminary examination for State-registered nurses. It could also be read with advantage by medical students and their seniors. After a brief outline of modern psychological theories the nurse is shown how this can be applied to the whole gamut of the *patient's* experience of illness and hospital life; so that she is led step by step to a realisation of how psychology can be of real use in understanding and ministering to her patients. The chapter on Some Special Problems is particularly good and deals with the surgical case, preparation for operation, anæsthetics, the care of the patient after operation, alleviation of pain, getting up, the use of sedatives and hypnotics, patients' questions about dying, the long-stay case, the elderly patient, and relatives and visitors. There is also a good chapter devoted to the nursing of children; the need for avoiding unnecessary separation of the young child from its mother is emphasised, though not, perhaps, forcibly enough. Some account of the good results obtained in children's wards where the mother is encouraged to visit daily and assist with settling the child down for the night might well have been included.

The whole book is written around the patient (a fact which is not suggested by the phrasing of the title) and this is specially commendable.

Nutrition and Climatic Stress

H. H. Mitchell, professor of animal nutrition, University of Illinois; Marjorie Edman, instructor in animal nutrition, in the university. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1951. Pp. 234. 50*s.*

This monograph was originally written for the United States Armed Forces, to summarise what is known of the influence of nutrition on the ability of men to endure climatic stress. The subject has an obvious bearing on the proper rationing of troops; but, as the authors point out, it has much wider implications than that. They have studied and summarised a great deal of work, published before October, 1949, on diet in a cold environment, a hot environment, and at altitude. Each section begins with the physiological effects of the form of stress under consideration, and then gives an account of what is known of the effects of this stress on nutrient requirements in animals and man. The very large bibliography refers mainly to American work, but some other sources are quoted. At the end of each section the authors have weighed up the evidence available at the time, and have offered some practical conclusions—such as that carbohydrate, especially when backed up by fat, is more effective than protein in keeping out the cold, that there is no statistical evidence to show that men voluntarily eat less protein in hot climates, that vitamin supplements seem to make little difference to tolerance of either heat or cold, and that for those going up to 15,000–17,000 feet carbohydrates are the thing, though perhaps inclined to cause trouble from flatus. A table occupying 16 pages summarises the effects recorded of treatments other than nutritional on altitude tolerance, noting the subject (whether animal or human) used, and the results. This shows at a glance which measures look promising and which may as well be given up. It also bears out the authors' contention that animal experiments do not offer a satisfactory guide to human nutritional requirements.

Human Nature

Its Development, Variations and Assessment. John C. Raven, M.Sc. London: H. K. Lewis. 1952. Pp. 226. 12*s.* 6*d.*

In this book Mr. Raven, the author of the well-known Progressive Matrices test, gives a good introductory account of the development of human personality from birth to maturity and old age. His style is leisurely and reflective, and much of what he says will stimulate the reader to fresh thought on well-worn topics, without ever shocking the most devout disciple of William James or McDougall. The section on mental testing in its various forms, with the assessment of their value, is authoritative. An appendix deals with the statistical techniques used in psychology, but even this is palatably administered. The book includes references to further reading at the end of each section, and a useful glossary and index.

Fitness and Injury in Sport (London: Skeffington. 1952. Pp. 189. 16*s.*).—During the last few years a number of books have appeared on the subject of athletic training written by men who must have had considerable practical experience in the preparation of athletes and in the prevention and treatment of injuries. Their aim, they invariably say, is to convey to athletic trainers in simple language the essential scientific principles and their application. That is a praiseworthy ideal, but in their anxiety to emphasise "the scientific approach" they usually include details of anatomy, physiology, and pathology out of all proportion to the requirements of potential readers. The difficulty is that moderate knowledge of a subject like physiology does not equip anyone to write a simple treatise for a layman, for this is one of the most difficult of all scientific literary achievements, and demands the profound knowledge of a professor.

There are so many flowery bypaths into which a writer can stray, and Mr. S. S. Knight, who is general secretary of the Physiotherapists' Association, unfortunately strays a good deal. Thus in the chapter on Food and the Athlete he begins by saying that "there is no known or certain way of improving athletic performance by means of food," and ends 14 pages later with the remark: "it is my experience that it is what you like in food that does you good providing there is enough of it." This being so, he might as well have omitted the intervening account of food analyses and calorie values. Nor does he make up for this waste of space in the section on prevention of injuries, for practical details here are scarce. He gives a brief but good summary of modern ideas on physical fitness. His proposed course for athletic trainers would occupy four to five terms, each of 12 weeks' full-time study. It seems a lot.

Proceedings of the Third International Congress of the International Society of Hematology (London: Heinemann Medical Books. 1951. Pp. 593. £3 10*s.*).—This is the English edition of the proceedings. It does not differ at all from the American edition, edited by Dr. Carl V. Moore, reviewed in *The Lancet*, 1951, ii, 868.

Interrogation (Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1951. Pp. 164. 35*s.*).—Captain Harold Mulbar is a senior officer of the Michigan State Police who has had much experience of getting at the truth by interrogating reluctant people. He has written, in admirably direct style, a well-informed guide to the practice of this art. Besides describing the procedures and artifices of ordinary questioning within the American police system, he gives much sensible information about the use of the polygraph, in Chicago and elsewhere, for "lie detection." His book is eminently practical, full of wrinkles and warnings, and assumes throughout that the investigator will have to produce his evidence for an American court. He is outspoken in condemning third-degree methods, which, it seems, might better be called torture and brutality.

THE LANCET

LONDON: SATURDAY, NOV. 1, 1952

Isoniazid

It is little more than six months since the news of the antituberculous action of isoniazid (isonicotinic acid hydrazide) and some of its related compounds was announced, but much work has already been published both on the clinical and on the laboratory side. As a result, certain preliminary conclusions have been fairly well established,[1] and they can now be examined in the light of two trials which have lately been undertaken in this country. The first and larger of these is described in an interim report[2] of the Medical Research Council's tuberculosis chemotherapy trials committee; and the second, a combined clinical, pharmacological, and bacteriological investigation at Guy's Hospital, is reported in three articles which we publish this week.

For the initial stage of the M.R.C. trial, 331 patients suffering from very different degrees of pulmonary tuberculosis were divided into two groups: one group of 173 patients received isoniazid (alone), and the remaining 158 had streptomycin and *p*-aminosalicylic acid (P.A.S.). After three months' treatment the isoniazid group showed an average gain in weight of 11 lb. compared with 6 lb. in the streptomycin-P.A.S. group—a highly significant difference. On the other hand, there was little difference in the response to treatment as judged by general condition, erythrocyte-sedimentation rate (E.S.R.), temperature, and radiological appearances. The M.R.C. report concludes that "judging wholly from short-term results . . . isoniazid is a very effective drug in pulmonary tuberculosis; but given alone it is not more effective than streptomycin plus P.A.S." Further reports are promised on the results of this investigation and on the various trials of combined therapy which are now in hand.

In the meantime, the clinical trial started by Dr. Joiner and his colleagues at Guy's Hospital carries us a good deal further. It is much smaller than the M.R.C. investigation, but it has certain features which make an interesting contrast. "Clinical assessment, sedimentation-rate, and weight estimation were recorded weekly by the same physician, while specimens of sputa from each patient were examined twelve times each month, so that the criteria for a negative microscopic result were strict." The patients corresponded to group 3 in the M.R.C. trial—the chronic type of patient who lives in "unhappy symbiosis with the organism" or whose general condition is slowly deteriorating. The conditions of the trial were "those under which most patients suffering from the type of disease have to be treated today." A preliminary investigation was designed to test the effect of isoniazid given alone for a very short time. Capsules of isoniazid (250 mg. per day) were given to 12 patients for six weeks, while another 10 had identical capsules of lactose. During the six weeks several patients in the first group showed a striking improvement in their general condition: they put on weight, and the number of tubercle bacilli in their sputum fell, though the changes in E.S.R. and in X-ray appearances were slight. In the control group most patients slowly lost ground. At the end of the six weeks the 10 patients who had been having lactose, together with 1 newcomer, were started on a course of isoniazid (250 mg. daily) plus 1 g. of streptomycin six times a week: the 12 patients who had been having isoniazid alone continued as before. The progress of these two groups was then assessed for eighteen weeks in all, and they showed definite differences. Isoniazid alone, even in the rather low doses used, produced in the first four or five weeks a striking improvement in most cases; but the effect on the sputum was only temporary, for some patients were already relapsing by the fifth week, and isoniazid-resistant strains were cultured from their sputum. On the average these patients gained weight until about the twelfth week; thereafter their weight remained stationary and their clinical condition began to deteriorate. On the other hand, those treated with isoniazid plus streptomycin not only showed the same initial response but maintained their improvement throughout the eighteen weeks; their general condition got steadily better, their weight continued to go up, the E.S.R. went down to normal in most cases, and the sputum-count showed very few bacilli or none at all. Another group of 16 patients was investigated: 9 had isoniazid plus streptomycin and 7 P.A.S. plus streptomycin. Both groups showed about the same improvement in clinical condition, in E.S.R., and in sputum-count during fourteen weeks' treatment, but those on isoniazid plus streptomycin gained much more weight than the others. Both these investigations at Guy's are continuing, and further reports will be published.

The Guy's results must be analysed by methods quite different from those used in the M.R.C. trial: each group of patients, though small, served in a sense as its own control. The patients who were treated with isoniazid alone, after a rather dramatic improvement, nearly all relapsed in an equally convincing way. Most of the patients in the initial control group were going slowly but steadily downhill, but this decline stopped immediately when treatment with isoniazid plus streptomycin was started; in fact they improved for the rest of the trial. An inspection of the record of each patient who had isoniazid plus streptomycin shows the characteristic "triple response" of gain in weight, fall in E.S.R., and decrease in sputum-count. Clearly the conclusion to be drawn from this clinical trial is that isoniazid alone cannot be recommended as a treatment for pulmonary tuberculosis, but that isoniazid plus streptomycin promises to be highly effective. This conclusion finds support in the field of experimental chemotherapy. The pharmacological branch of the work at Guy's Hospital has dealt with the effect of isoniazid, alone and in combination, on experimental tuberculosis of the cornea in rabbits and mice. The methods used have already proved valuable in examining the merits of promising antituberculous drugs.[3] On another page of this issue, Dr. GOULDING and Professor ROBSON describe how the development of corneal tubercles in mice inoculated intracorneally with a virulent strain of *Mycobacterium tuberculosis* was completely arrested while the mice were having isoniazid; but the lesions appeared after the usual interval when the drug was stopped. With streptomycin alone the disease was almost entirely prevented, though occasional lesions appeared even during treatment; and when the streptomycin was stopped, it was uncommon for lesions to develop later. But a combination of isoniazid and streptomycin was much more efficient, and no lesions developed at all either during or after treatment. A combination of P.A.S. and isoniazid was no more effective than isoniazid alone.

[2] *Brit. med. J.* Oct. 4, 1952, p. 735.

In the third paper of this series Professor KNOX, Dr. KING, and Mr. WOODROFFE describe their work on the in-vitro action of isoniazid on the tubercle bacillus. They found that the apparent sensitivity of *Myco. tuberculosis* to isoniazid in Dubos liquid medium depended on the length of incubation of the culture, and for that reason a standard period of incubation was essential. When the sensitivity was read after incubation for fourteen days or less, growth was usually inhibited by a concentration of 0·01 µg. per ml. (1 part in 100 million). With longer periods of incubation, growth was eventually seen in tubes which originally contained up to 1·6 µg. per ml. They have shown that this unstable end-point is the resultant of two processes: (1) an inactivation of the drug, even in uninoculated Dubos medium at 37°C; and (2) a selection of organisms with increased resistance to the drug. In another article in this issue, Dr. MITCHISON reports a similar inactivation of isoniazid in uninoculated Dubos medium at 37°C, and a comparable shift in the end-point in the inoculated medium. Commenting on the difficulty of deciding with certainty whether a drug is mainly bactericidal or bacteriostatic, KNOX and his colleagues say that the in-vitro action of isoniazid was profoundly modified by quite small changes of temperature, and they suggest that a rise of temperature from 37° to 40°C increases its bactericidal action. They think that this is no mere test-tube phenomenon, for isoniazid has a miraculous effect on toxic patients with high temperatures, and, moreover, GOULDING and ROBSON found interesting differences in the action of isoniazid on animals with different body-temperatures. The laboratory evidence, though not yet complete, suggests that isoniazid alone, in vitro, and in concentrations close to those which inhibit growth, is bacteriostatic rather than bactericidal; that resistant variants can be quickly and easily produced; and that a combination of isoniazid and streptomycin is more nearly bactericidal and delays the development of strains resistant to both drugs.

All this evidence points to the same general conclusion: the initial attack of isoniazid on the tubercle bacillus is perhaps the most powerful of all the weapons yet discovered, but the drug must not be used alone except for very special reasons. Attention is now being concentrated on the urgent question of how best to combine it with other drugs. The final answer is most likely to come from extensive clinical comparisons of the kind started so promptly by the M.R.C.; but valuable information can be gained and a great deal of time saved by smaller combined investigations on the Guy's pattern.

Management of Disseminated Sclerosis

NOWADAYS associations of patients suffering from a particular disease, and of those interested in their welfare, are springing up, and doing good service by passing round useful information. One such association, the National Multiple Sclerosis Society of America, was founded in 1946 by a group of physicians and patients to stimulate research into the demyelinating diseases in general and disseminated (multiple) sclerosis in particular. This society, which has already sponsored some thirteen research projects in university hospital centres in the United States, has now published five important manuals by Dr. EDWARD E. GORDON, of the department of physical medicine and rehabilitation of the Bellevue Medical Center, New York University. One is addressed to doctors, while the other four, addressed to patients, are home programmes for those confined to bed, those who can manage life in a wheel-chair, those able to walk with mechanical aids, and those able to walk alone.[1]

The striking thing about these publications is their hopeful and confident attitude towards a disease which we in England are apt to regard despondingly. Dr. CORNELIUS H. TRAEGAR, medical director of the society, in his foreword to the home programmes points out at once that the life-expectancy of these patients does not differ much from that of normal people, and is a great deal longer than that in most other chronic diseases. Instead of speaking vaguely of "remissions of varying duration" he declares roundly that great numbers of patients, at first severely disabled by the disease, have recovered spontaneously, either wholly or in part. These are no mere encouraging tales for patients; much recent work supports them[2]; and Dr. GORDON reiterates them in his introduction to the manual[3] addressed to doctors, and adds this important statement:

> "Since doctors are not prophets it cannot be predicted that the termination of a given acute episode is not the last of the disease for a given patient. When a patient with multiple sclerosis recovers from an acute episode, the doctor, for the purpose of rehabilitation, must *promptly* and *enthusiastically* begin a programme of rehabilitation."

This manual discusses in detail how the patient may be taught to live his life in spite of his handicaps, by exploiting his remaining powers. It is a programme demanding hard work from both patient and doctor. The chief enemy of the patient's life is infection—bronchopneumonia, bladder sepsis, bedsores—and the strong ally of infection is inactivity. The doctor's duty, then, is to get the patient on the ove and keep him moving. The first thing to do is to ssess the degree of disability; and in Dr. Gordon's iew this is no matter of getting a rough general idea. The manual includes a chart which can be used for rading spasticity, strength, and range of movement f the joints of the upper and lower limbs, neck, and runk. The completed chart serves for comparison t the next examination. Spasticity is of particular nterest, not only because it varies according to the osition and previous activity of the patient but also ecause it is increased by anxiety. If the patient's motional difficulties—whether these preceded the ppearance of his disorder or are its outcome—can e resolved, his general tension may be much reduced nd with it his spasticity. Other methods of lessening pasticity include gentle stretching, heavy exercise f the unaffected muscles, and in a few cases special races designed to increase the patient's skills. Weak nuscles are easily fatigued, and in a series of trials heir power may progressively decline. Such a decline an be recorded in figures, as 4→3→2→1, where 5 is ormal, 4 good, 3 fair, 2 poor, and 1 a trace or a light muscular contraction with no motion. In ddition, it is important to note contractures, and ny weakness due to overstretching in the antagonists f contracted muscles. The degree of ataxia and ncoördination may be difficult to evaluate if obscured by muscular weakness or spasticity; Dr. Gordon thinks it more useful to concentrate on the activities of daily living. Thus a positive Romberg test gives information about standing balance; but it is more useful to know whether the patient can stand safely with his feet a little apart and his eyes looking ahead than that he falls when he has his feet together and his eyes shut.

[3] Multiple Sclerosis: Application of Rehabilitation Techniques.

Activities depending on body position include, for example, ability to roll to either side in bed, to sit up, to get out of bed or out of a chair and stand, to sit down in a chair or a wheel-chair from the standing position, and to get down on the floor and up again. Those depending on reach and grasp include ability to dress, tie the shoelaces, brush the hair, eat with a knife and fork, write, telephone, and turn a tap. For those using a wheel-chair progression depends among other things on the ability to get into and out of the chair, propel it, and move from it to the toilet seat and back again; while for those walking with or without crutches progression depends on the ability to walk forwards, backwards, and sideways, to open and close a door, and to go up and down stairs. These and similar activities are charted, with the date on which each is achieved—a great encouragement to the patient.

The reablement programme is energetic and directed to clearly defined ends. The patient, Dr. Gordon reminds us, expects to find in his doctor a strong and resourceful counsellor. Objectives will differ according to the patient's physical status—whether he is confined to bed, restricted to a wheel-chair, able to walk with aids, or able to walk alone. If he is bedfast and cannot sit, it is pointless to begin by teaching him to use a spoon: he must first learn to sit up in bed. If he can sit in a wheel-chair he must learn to reach and grasp before he learns to walk.

To take a specific example, suppose a patient who can sit up is clumsy at carrying food to his mouth. The first step will be to study the muscle-groups which subserve grasp, supination, flexion on the elbow, and abduction of the shoulder, and to treat them for any weakness, spasticity, or contractions which may be present; the second step is to give the patient integrated training in performing the whole motion under realistic conditions. If incoördination is also present, then training in coördination must be included. If these measures produce no change for the better, it is time to think of mechanical devices to help him over the difficulty—e.g., aids for grasping, and for lifting and stabilising the arm.

The doctor must not overwhelm the patient with responsibility for his entire course of training: he must present him with attainable objectives, one or two at a time. The patient has his own responsibility—to carry out faithfully the exercises the doctor prescribes; and details of how he is to do it, and what simple equipment he will need, are set out in the home programmes.

A simple pulley with two stirrup-shaped handles can be used to exercise the arms; and if the patient cannot grasp the handles he can wear a glove which straps the fingertips down to a wristband and so holds the hand closed. One stirrup can be replaced by a child's bucket holding graded weights, and the arm can then be exercised against weight resistance. Coördination can be practised by moving small objects to numbered squares on a chessboard, and by the use of Montessoric apparatus designed to give practice in fastening buttons, tying laces, or fastening hooks and eyes.

We are too apt, in dealing with these patients, to think of failure of function in purely structural terms, forgetting that the conscious person in charge of the structure can find ways of getting round a difficulty, and moreover that the nervous system is wonderfully adept in spreading its tasks among the available neurones, much as a hospital matron during a staff epidemic deploys her remaining nurses. The patient with disseminated sclerosis can and should work at his own reablement; and Dr. Gordon is not among those who think heavy exercise will harm him. He points out that studies of cases of lower-motor-neurone injury have shown that fatigue does not interfere with axon regeneration.

Mechanical aids may be used in two ways—either to start a patient off in acquiring the next skill (thus a crutch and leg-irons may help to start a patient walking, though he may be able to discard them later), or as a substitute for a power finally lost.

Dr. Gordon advises on crutches and crutch gaits, leg braces, night splints for hands, wrists, and legs, types of wheel-chair, sling suspensions which allow patients to use weak hands, devices for holding spoons and knives and forks, a knife and fork conjoined, long spoons and forks conjoined at an angle, thick-handled pencils, cups with lids perforated so that the patient can drink without fear of spilling, pivoted arm-rests, long shoe-horns, supported telephones, lazy-tongs, and many other simple and useful tools to help these patients to help themselves.

The whole tone of these manuals is inspiriting, and should start many doctors thinking afresh about the care of their patients with this disease. As Dr. Gordon puts it, "the techniques and devices developed in the field of rehabilitation can be employed so that the patient's life may be made productive; if not productive, self-dependent; and if not self-dependent, at least tolerable." The National Multiple Sclerosis Society send the appropriate manuals to doctors or patients without direct charge, though they mention that subscriptions to further their work will be welcome.

Control of Filariasis

FILARIASIS, due to *Wuchereria bancrofti*, is a scourge of most of the hot and damp parts of the tropics; but it can now be hopefully attacked in two ways—by destroying the worms with dimethylcarbamazine ('Hetrazan,' 'Banocide') or by destroying the mosquitoes (which transmit it) with insecticides. Progress on these lines is now being made in different parts of the world. On another page a correspondent describes what is being done in Tahiti, where a joint American and French team are studying modern methods of control.[1] In that island, it seems, a third of the population over 5 years old carry microfilariæ in the blood, and 8–20% of the men between 30 and 50 years of age suffer from elephantiasis. Small experimental areas each containing about 60 persons were treated by various combinations of dimethylcarbamazine, general sanitation, and D.D.T. The dimethylcarbamazine was given as 2 mg. per kg. body-weight three times a day for seven days. (This schedule must have been difficult to supervise to ensure that all doses were actually taken.) A year later the percentage of people with microfilariæ had fallen from 34 to 20 and the microfilarial density in those remaining positive had fallen to less than 10% of its original level. The treatment, however, did not reduce the frequency or severity of clinical filariasis. The drug is said to have been well tolerated, though more than half the patients suffered transitory reactions on account of the compound itself or of allergic reactions to the microfilariæ which had been destroyed. Presumably the people were conscious of the dangers of the infection and so were prepared to undergo some discomfort in order to be rid of it. The other measures, of sanitation and of spraying with D.D.T., did not have an effect upon microfilarial rates or densities in the course of a single year, though they probably reduced the mosquito population. These are measures which act slowly, and their full benefit cannot be estimated soon.

A trial of dimethylcarbamazine which was restricted to a single village of about 700 persons has been reported from the Gambia in West Africa.[2] A preliminary survey by blood films taken at night showed that 40–54% of the people over 10 years old carried *Mf. bancrofti*, but only 6 (about 1%) showed signs of elephantiasis, or hydrocele. Dimethylcarbamazine, 5 mg. base per kg. once daily for five days, was administered under strict supervision to the microfilaria carriers. A year later 64% of the treated carriers had become free of microfilariæ and the total microfilaria count was reduced by 94% (9% of people previously free from microfilariæ now showed them). Some of the patients who had been treated with the drug had also contained *Mf. perstans*, and a year later the total microfilaria count for *perstans* had been reduced by 90%. Although *perstans* is non-pathogenic and so unimportant, this demonstration of the action of dimethylcarbamazine on it is interesting. Unfortunately many of the persons receiving the drug experienced minor toxic reactions such as headache, nausea, or anorexia. Very few of these were sufficiently severe to have been noticed by inpatients at a hospital; but among healthy villagers, who were not much *conscious of filariasis or its sequelæ*, they were enough to cause great reluctance to complete the course of treatment. In villages where the doctor was not personally known and trusted, they would make such mass-treatment impossible. In this investigation it was concluded that dimethylcarbamazine (in this dosage) had been effective in greatly diminishing the potential transmission of the infection, but its unpopularity and expense would be great handicaps to widespread use.

From East Africa comes the annual report of a research unit set up in 1949 by the Colonial Medical Research Committee under the High Commission of East Africa for the study of filariasis.[3] This report covers a wide field. Much attention has been devoted to the optimum dose schedule for dimethylcarbamazine and to its absorption, blood concentration, and excretion. Two field trials have been begun, one at Kyela near Lake Nyasa and another on the island of Ukara in Lake Victoria. *In the first a total dose of* 70 mg. per kg. (divided into two-hourly doses) was given during a single day. This caused much vomiting; and for practical use the report recommends a dose of 0·5 mg. base per kg. per hour so that a total of 35 mg. per kg. is given during three days. (This was the dose which was used for most of the patients on Ukara.) Fifteen months later the total microfilaria count at Kyela had been reduced by 96% although 80% of the patients still contained a few microfilariæ. The results on Ukara were similar, though the period of follow-up is not yet so long. The expense of such treatment would, however, be a serious obstacle to its wide use. As was expected, dimethylcarbamazine had no effect on clinical filariasis, hydrocele, or elephantiasis. Trials were also made of an antimony compound called 'Protostib,' which is pentavalent N-methyl glucamine antimoniate. This was given intramuscularly to 164 patients in doses as high as 20 ml. of the 30% solution daily for ten days. In 4 cases the patient developed mild and transient exfoliative dermatitis, but none the less the treatment seems to have been popular among the local inhabitants. There has not yet been enough time to evaluate the full effect of this treatment, which is designed to destroy the adult worms; but after four months there was a diminution of the total microfilaria count by 50–80% and the general outlook is promising. However, this treatment is too expensive and too toxic for use in field eradication work.

During filarial surveys, microfilariæ of *bancrofti* were found in 2 infants of less than 12 months old, who must be the youngest carriers yet recorded. Attempts to facilitate the diagnosis of the infection by antigens—e.g., by skin reactions or complement fixation—were unsuccessful; both these tests were unreliable. Dimethylcarbamazine has also been used to treat onchocerciasis (a disease which is important because of the blindness it causes); but a more effective way of controlling this infestation seems to be the eradication of the vectors, *Simulium neavei* and *S. damnosum*, by treating infected streams with D.D.T.

Altogether the present work on filariasis is remarkable for its wide geographical distribution, its diversity, and its promise of ultimate (though perhaps delayed) success.

Annotations

NOBEL PRIZE

Prof. Selman Waksman, director of the Rutgers University institute of microbiology, New Brunswick, has been awarded the Nobel prize for medicine and physiology for the discovery of streptomycin. This discovery, in 1943, was the outcome of work begun in 1915, when Professor Waksman found in soil the actinomycete later named [illegible]. He has since developed neomyci[illegible] *fradiæ.*

TRANSPYLORIC PROLAPSE OF THE GASTRIC MUCOSA

Radiological examination sometimes shows an inconstant filling defect in the base of the duodenal cap, resembling a mushroom, cauliflower, or umbrella, due to linear folds of gastric mucosa passing through the pylorus and, as it were, pouting into the duodenum. This pouting is inconstant in shape and it may be present only during antral contraction; serial radiographs show a continually changing pattern that can be further modified by pressure over the antrum or duodenal cap and by altering the position of the patient.

As long ago as 1923 Forsell[1] drew attention to the mobility of the mucosa on the muscular wall of the stomach and to its independent changes in shape. Soon afterwards it was shown[2] that prolapse of the gastric mucosa through the pyloric sphincter into the duodenum could be recognised radiologically and confirmed at operation. As often happens with radiological appearances, increasing familiarity has been followed by reports showing an increasing proportion of positive findings. Thus, Rees[3] found 4 instances in 3000 patients, Scott[4] just over 1% in 1000 patients, Ferguson[5] 7% in nearly 300 patients, and Rappaport et al.[6] 15·5% in 1000 patients. In this country New[7] has reported this change in nearly 3% of 1700 patients, while in Belgium Wellens and Spyckerelle[8] found it in 5% of their patients. Rappaport et al. cite a case in which characteristic appearances were seen in only one of fifteen radiographs of the pyloric antrum and duodenum; and such inconstancy suggests that sometimes the normal is being confused with the abnormal.

Manning and Gunther[9] described six cases of mucosal prolapse examined post mortem. In none of these did this disorder account for death, though in 1 gastric hæmorrhage was a contributory factor. In 5 cases the antral rugæ were thickened, hypermobile, and redundant, with microscopic evidence of mild to severe chronic inflammation in the mucosa or submucosa. In 1 case congestion and multiple small superficial ulcerations were present on the prolapsed folds. Thickening of the pyloric muscular ring with apparent narrowing of the pyloric canal was seen in 4 of the 5 cases examined microscopically. In 4, the entire circumference of the pyloric mucosa was involved in the prolapse; the other 2 showed only tongue-like projections.

Norgore and Schuler,[10] described 2 cases treated by partial gastrectomy on account of vomiting and epigastric pain made worse by solid foods. Levin and Felson[11] found 18 cases of prolapse in 100 patients with no digestive complaint. Of the 1000 patients examined by Rappaport et al., only 28 had no gastro-intestinal symptoms, and of these 3 showed mucosal prolapse; of 118 with lower abdominal symptoms only 16 had mucosal prolapse; while of 854 with upper abdominal symptoms 136 had prolapse. The proportional differences between the three groups are small. Of the 155 patients with mucosal prolapse 91 showed one or more further definite abnormalities in the gastro-intestinal tract; hiatus hernia, cholecystitis or gall-stones, and peptic ulcers were the most common. Of the remainder 39 had chronic recurrent dyspepsia consisting of periodic epigastric fullness, generally after heavy or spicy food, flatulent discomfort, and heartburn; discomfort was felt soon after a meal and actual pain was rare. Bicarbonate of soda gave much relief, but aluminium hydroxide gel gave little. Gain of weight before the onset of symptoms was not uncommon. All these 39 patients had notable evidence of neurosis, and said that their symptoms were often induced by emotional disturbance. 4 patients (not all in this series) were treated surgically, but relapsed afterwards. A further 25 patients in the series with positive radiological findings had only transient epigastric discomfort or no upper abdominal symptoms at all. Gastric analysis and gastroscopy gave no definite information. As in New's[7] series the appearances were more often seen in men than in women, and were most usual in the fourth and fifth decades.

It thus seems that prolapse of the gastric mucosa into the duodenum may give rise to either no symptoms at all or to mild symptoms, especially in the neurotic. There is no evidence that this disorder is a hazard to the patient's life.

GENERAL PRACTICE IN SCOTLAND

The Scottish Medical Practices Committee issued its fourth report this week. The committee welcomes a substantial increase in the number of principals in practice: on July 1, 1952, there were 2379 doctors providing general medical services in Scotland, compared with 2328 a year before; and of this year's total 2127 also provided maternity medical services, as against 2063 in 1951. The latest figures show that the average number of patients per doctor in Scotland is about 2150; the corresponding figures for England and Wales at the beginning of this year give an average of about 2400 per doctor, but, as the annual report of the Ministry of Health[12] points out, the total number of patients on doctors' lists is still inflated by duplicated and out-of-date entries. Moreover the Scottish average is reduced by the figures for the isolated areas where a doctor is needed even though his list is very small; the doctor on the island of Coll, for example, has a list of only 209. There are many places, chiefly in the industrial areas, where doctors still have more patients than the committee thinks desirable, and the report hopes that when the proposed changes in the distribution of the central pool come into effect, new doctors will find it easier to gain entry into established practices in these areas.

On the question of ways into general practice, the evidence before the committee in the past year has strengthened its view that "the likeliest method for a young doctor to establish himself in general practice is to be assumed into partnership, preferably after an initial period of assistantship." Doctors who have set up new and independent practices (even in districts which had been included in the list of underdoctored areas) have often, in the committee's experience, had a hard time of it, and the proportion of doctors who apply to start practice on their own account is decreasing. The committee granted 148 applications for admission to executive councils' lists during the year under review, and only 31 of these were from doctors going into independent practice, whereas in the previous year the proportion was 20 out of 74.

Scottish executive councils advertised 25 practice vacancies during the year, and they received over 500 applications. There were not, of course, over 500 doctors looking for a permanent place in general practice, because many were applicants for more than one vacancy; but nevertheless "the Committee have been concerned to note the difficulty still experienced by many doctors anxious to become settled as principals." Roughly 70% of the applicants were already engaged in general practice, either as assistants or as principals who sought to change the type or locality of their practice; 10% were hospital doctors; 10% were doing locum appointments of various kinds; and the remaining 10% were employed in the public-health service, Government medical services, and comparable work. A further analysis of 21 of the advertised vacancies shows that 17 of them went to doctors under the age of 40. The corresponding committee for England and Wales observed last year[13] that, in the matter of openings in general practice, "the scales are now more than balanced fairly in favour of the younger doctors"; and the position in Scotland justifies the same remark.

SALINE INFUSION

In his challenging letter on p. 883, Dr. Murphy raises the question whether we are allowing patients to die for want of adequate saline infusion. He dismisses the dangers of overloading the circulation as a bogy, at any rate in patients with no primary cardiac or renal failure. He points out that normal people can readily get rid of large loads of salt and water; and he might have added that normal people can withstand infusions of saline, plasma, or blood up to 2 litres without any notable symptoms.[14] The weakness of his argument lies in the implied transfer of the homœostatic powers of a healthy person to one who has just sustained a major operation. There is clear evidence that in the post-operative period both water and salt are excreted abnormally slowly;[15] and the patients are in the grip of a major metabolic disturbance.[16] Pathologists are familiar with the sodden lungs of patients exposed to excessive intravenous saline, even when that unfamiliar tool, the stethoscope, has not revealed pulmonary œdema during life.

The crux of the matter would seem to lie in accurate diagnosis of salt depletion before beginning treatment. There is no excuse for saline treatment as a routine post-operative measure, and little doubt that saline infusion can be dangerous to a patient who is not salt-depleted. In the salt-depleted patient, on the other hand, saline infusions are well tolerated and beneficial, and the amount of saline required to restore circulation and well-being may, as Dr. Murphy claims, be very large. The diagnosis of severe salt depletion must be based on a history of salt loss (usually from the alimentary tract, but sometimes in the urine, as in diabetic coma) and on clinical dehydration and collapsed veins. In severe salt depletion the serum-sodium is low, and chloride is often absent from the urine. Given the clinical context and the signs of serum-sodium depletion, it is safe to press on boldly with saline infusion. The deficiency of sodium associated with severe dehydration is of the order of 1000 m.eq., representing some 60 g. of salt. Saline infusion on this scale is only justified by an accurate previous assessment of the deficit. In patients with acidosis about half the necessary sodium should be given as lactate; and potassium should also be given during massive saline infusion, which increases the urinary excretion of potassium. Potassium should be administered by mouth when possible; but the greatest problems of electrolyte replacement arise in patients with paralytic ileus or fistulæ, and for these intravenous potassium may be needed. Cooke and Crowley[17] have lately given a practical account of the management of electrolyte loss from the gastro-intestinal tract.

So far as electrolytes are concerned, improved post-operative management depends on taking more care with the individual patient and adjusting our treatment to his needs, so far as we can discover them.

ONE MAN'S MEAT

In the days when travel was possible, one could leave one's customary diet of bread and tea to travel north and eat scones and haggis. One could then cross the sea for the pastries and dairy produce of Denmark, go south for the crêpes and snails of France, and on for the potatoes and beer of Germany, and then either east for the rice and chow-mein of China or west for the breakfast cereals and soft drinks of the U.S.A.; one could even taste the corn and fat-back of the southern States before passing into Mexico to gorge on tortillas and chillies. Nevertheless, these foods of civilised peoples are all much of a muchness. It is among less civilised races that diet becomes either very monotonous or very varied: very monotonous if only one foodstuff is to be had throughout most of the year (as with Eskimos), or very varied if one downs almost anything that can be chewed and is not subject to a taboo.

On Oct. 18 the Nutrition Society devoted a day to the discussion of unusual foods. Some would have us eat grass (euphemistically called leaf protein), some green algæ, some synthetic fats made from coal. Mr. W. A. P. Black, PH.D., stated the case for seaweed. To the analyst this seems an excellent food: 15% protein, some fat, a high mineral content, a liberal supply of vitamins including apparently vitamin B_{12} (or cyanocobalamin as we now should call it), and plenty of agar to add bulk. Furthermore it contains not only 1% iodine but also 3 : 5-diiodotyrosine ready-made for the thyroid. However, the dietists present were not told how to cook it. Should it, one wondered, be fried in deep fat, or perhaps be chopped, boiled, and served with grated cheese? Mushrooms and toadstools were championed by Mr. J. Ramsbottom, D.SC. In any country other than this such fungi would not be classed as an unusual food; and the widespread fear of them is not justified, since only *Amanita phalloides* and two related types are poisonous. Mushrooms are not rich sources of nutrients, and only the epicure would pay the price of 16*s.* a pound which was reached in the war. Probably Dioscorides was right in classifying mushrooms into those which were poisonous and those which were not, and leaving it there. After this vegetarian start the meeting passed to a meat dish with an authoritative discourse on insects as food from Mr. W. S. Bristowe, D.SC. A zoological blind eye was apparently turned on this address, which was more about spiders than insects. The important point was that "insects" taste nice: the flavour of the lizard is musty, but a giant water-bug tastes like a strong gorgonzola, only more so; the so-called "bird-eating" spider, without its jaws and toasted, tastes like excellent marrow, and there is quite a lot to be said for boiled locusts. The question of taste was obscure to Mr. A. L. Bacharach, who thought that the "meaty" flavour was always accompanied by a backbone and that invertebrates always tasted vegetable.

Mr. F. Aylward, PH.D., described investigations by the Massachusetts Institute of Technology into the excellent dietary of the inhabitants of Central America; the plants eaten by the Mexicans are much richer in nutrients than are those in the U.S.A. Dr. H. M. Sinclair then took the meeting to visit the Eskimos and Canadian

Indians. From the dietary of seal and fish consumed by Eskimos a century ago he calculated the aliments and nutrients obtained. It seems that they fared very well provided they could catch the seals, and there was certainly no deficiency of vitamins. Although the diet was very rich in protein, rich in fat, and poor in carbohydrate, there was no reason why it should give rise to ketosis; but it was perhaps surprising that arteriosclerosis was so rare. Indeed, the other diseases of civilisation (such as diabetes mellitus, tuberculosis, appendicitis, cancer, and dental caries) were extremely rare among the Eskimos, and still are in those few places where they have not been contaminated by white men. Importation of the white man's diet brings with it his diseases. This has been particularly obvious in the case of the Indians: the Crees visited by Dr. Sinclair in 1943 used to be hunters subsisting on an excellent carnivorous diet; but now their dietary is mainly bannock, white flour, lard, and sodium bicarbonate, mixed together in haphazard proportions. This fate has also overtaken the Australian aborigines, whose food was discussed by Mr. G. H. Bourne, D.SC. Now they consume white flour and sugar, whereas previously they subsisted on various animals ranging from marsupials and buffalo to moths and caterpillars. In the last paper, Dr. B. M. Nicol discussed the protein in the diet of the Isoko tribe of the Niger Delta. Here again was a tribe largely carnivorous in habits who consumed fish, snails, snakes, and lizards; but to these they added yams, cassava, palm oil, and palm wine.

It is perhaps unfortunate that there was not enough time to correlate the dietaries of these different peoples with the incidence of diseases among them: this is a subject of great interest to which far too little attention has been paid. Sometimes dietary and culinary habits are dictated by expediency: the Eskimos obtain large amounts of vitamin C from the skin and stomach contents of the animals they eat, and most of their food is eaten raw. These habits arise, not from a knowledge of dietetics, but from the necessity of eating as much as possible of the slender food-supply and from the difficulties of cooking in an igloo. Physiologists might well study the Eskimo further, particularly when such interest is being taken in survival under Arctic conditions. And some of the problems appear to concern physicists; for Dr. Sinclair mentioned that the Yakuti are alleged to be able to eat 36 lb. of beef and 18 lb. of butter (about 120,000 calories) in under three hours. Throughout this interesting discussion it appeared that there were serious gaps in our knowledge, severe limitations in our choice and enjoyment of food, and a surprising difficulty in describing tastes. It is doubtful if we have advanced much beyond the problem of cooking a snark.

PORPHOBILINOGEN

PORPHOBILINOGEN, the Ehrlich-reacting material which appears in the urine of acute porphyria, has long been one of the veiled figures which haunt the course in clinical pathology. It has some diagnostic and prognostic interest to the clinician, but its main importance is its association with the whole subject of porphyrin chemistry. In this connection the biochemist has had it on the list of "wanted" substances for some time, and now a particularly elegant piece of research by Westall[1] has culminated in its crystallisation. This is a considerable feat, since the insolubility of porphobilinogen in most non-aqueous solvents and its instability make it very unmanageable. Its isolation has been made possible by the development of ion-exchange resins as chromatography media, and by the observation that porphobilinogen can be precipitated from urine by mercuric acetate.

Porphobilinogen has usually been thought to give rise, under certain circumstances, to uroporphyrin. This view, recently contested by Hawkinson and Watson,[2] has now been proved correct. The change takes place on boiling at any pH between 1 and 8, the largest yield being obtained in $0{\cdot}5N$ HCl. On standing at room-temperature, porphobilinogen is slowly converted to the reddish non-porphyrin pigment, porphobilin.

The importance of any substance which can give rise to porphyrin lies in the possibility that it may be a natural intermediate in porphyrin synthesis. The number of these known or suspected precursors is growing—recent work by Weatherall[3] at the London Hospital, for instance, strongly suggests that in the lead-poisoned rabbit all the urinary porphyrin is present as precursor at the moment of excretion. The nature of porphobilinogen has been the subject of several guesses. The most popular has been that it is a monopyrrole or more probably a dipyrrole—possibly a dipyrrylmethane of the type postulated theoretically as an intermediary in porphyrin synthesis. This guess can now be tested. Whether porphobilinogen in the urine is an overflow of a normal metabolite which is produced in excess, or whether it is in itself an abnormal material, cannot yet be settled. But some interesting light on porphyrin synthesis and on congenital errors of metabolism is likely to come from further work on porphobilinogen which is now in progress.

FIFTY YEARS OF MIDWIFERY

IN 1900, out of every 300 London mothers giving birth, one died; in 1950 one died out of every 1880. The first Midwives Act, which set in train the events which led to this extraordinary change, was passed in 1902; and on Oct. 28 the Royal College of Midwives entertained the Minister of Health at their celebration of the golden jubilee of this momentous piece of legislation. Before it was passed, as the *Manchester Guardian* (Oct. 27) recalls, women who could not afford to pay a doctor to attend them in confinement relied on the Gamp, who was sometimes kindly and experienced, but all too often cut to the pattern of the immortal Sarah. It is true that in 1872 the Obstetrical Society of London, after failing to persuade the Government to take action, started their own examination for midwives, though they could not compel women practising midwifery to take it; and when the Midwives' Institute, now the Royal College of Midwives, was founded in 1881 it immediately undertook the further training of women who held the Obstetrical Society's certificate. It took eleven years, and all the money the institute could raise, before the Act making it an offence for an uncertificated woman to attend a delivery (unless she was working under a doctor) reached the statute-book. The official qualification became the certificate of the Central Midwives Board; and after 1910 the board recognised the institute as a lecture centre for pupil and postgraduate midwives. The increasing work of the institute in the interests of maternity and child welfare led to its change of status, in 1941, to the College of Midwives, and in 1947 to the royal recognition.

Today the mother has many services at her command. The midwife, however, remains a key figure in the team, and may fairly take much credit for the fall in the maternal mortality-rate. Nor has her part been small in the saving of infant lives: since 1902 the infant-death rate has fallen from 133 per 1000 live births to 23 per 1000 in the third quarter of this year—the lowest figure on record.

THE ASSISTANT EDITOR OF THE LANCET

WITH great regret we announce that Dr. Edward Clayton-Jones, because of continuing ill health, has resigned. The Proprietors have appointed Dr. Ian Douglas-Wilson to succeed him as assistant editor from Nov. 1.

THE GROUP INTERVIEW IN THE SELECTION OF MEDICAL STUDENTS

M. L. JOHNSON
B.Sc., Ph.D. Birm.

HONORARY RESEARCH ASSOCIATE, UNIVERSITY COLLEGE, LONDON

THE suggestion has several times been made (Biesheuvel 1947, Millar 1948, Brinton 1951, Warburton 1952) that the group interview might be adapted for use in the selection of medical students, and it may, therefore, be of interest to record some experiments with it at University College, London.

It is a generally accepted principle that candidates should be interviewed before being offered a place in a medical school. This implies the recognition of the great importance of personal qualities in a doctor, and the assumption that these can be assessed by interview. The unreliability of the conventional interview has, however, often been clearly demonstrated—by Hartog and Rhodes (1936) for instance. Nevertheless the interview is probably the only safe way of choosing those candidates whose personal qualities recommend them for a medical career. The question then arises: how can the interview be improved, or supplemented, so that we can select more successfully?

One of the difficulties is that we are attempting to predict, from the candidate's behaviour at the interview, what his behaviour will be as a student and doctor—and he may behave very differently in different situations. This difficulty stimulated the development of some of the procedures used by the War Office Selection Board and the Civil Service Selection Board; here candidates are observed in situations more like those in which they will do the work for which they are being selected. There are obvious difficulties in using such methods for medical students, because we could not hope to test them for the skills that a doctor needs, but only for the capacity to develop these skills during their training. One way of meeting the difficulty is to extend the process of selection into the early part of the training period, as advocated by Brinton (1951). Another way is to watch the candidate in a number of different situations, so that his assessors get a better idea of the range of his behaviour; and various forms of group interview could be used for this purpose.

COMPARISON OF INDIVIDUAL AND GROUP INTERVIEWS

In the individual interview the candidate is seen reacting to one person, or to a board, and in general he is expected, and he expects, to behave as a junior to a senior. It is proper that his behaviour in this rôle should be tested, for a good deal of a student's time, and part of a doctor's, will be spent in this way. Most people, however, do not behave towards juniors or contemporaries in the same way as they do towards seniors—some people behave very differently indeed—so the value of such an interview, *in indicating how the candidate will* behave to patients or to colleagues, is limited.

In a group interview the candidate is seen in a much more complex social situation, for he is reacting to several other candidates, who are contemporaries, as well as to his assessors, who are seniors. Thus, the group interview samples the candidate's behaviour in a different social setting. It differs from the individual interview in another very important respect. The etiquette of the individual interview is fairly well established: the candidate usually speaks only *in answer to a question,* or when invited to make a statement; the assessor takes the initiative and the candidate responds. In group interviews, however, the candidate must form his own judgment of the situation and how to conduct himself. The assessor plays a much less active rôle, and the candidate a much more varied and autonomous one.

DEVELOPMENT OF THE GROUP INTERVIEW

Testing by various group methods was developed during the last war (O.S.S. Assessment Staff 1948, Harris 1949). Group interviews are now an established part of the Civil Service Selection Board procedure (Vernon 1950). They are also being used in several other ways—e.g., in the selection of applicants for training as teachers at Dudley Training College (Jordan 1950) and at Manchester University (Herbert 1951); in making various appointments in industry (Fraser 1950); in choosing dental students at Manchester University (Warburton 1952) and medical students in the U.S.A. (Wood et al. 1949).

GROUP INTERVIEW AT UNIVERSITY COLLEGE

The group interview can be used in different ways; the main aim may be to test leadership, or simply to see how well candidates get on together. For each purpose modifications of technique are of course necessary. In our interviews we were mainly concerned with testing social adjustment, and the ability to think effectively *about an abstract scientific topic.*

The candidates were interviewed in groups of eight, sitting round a table with two assessors. The selection procedure (Aitken and Johnson 1952) was explained, and we told them that we were trying this rather complicated method of three interviews because candidates often felt that in the usual interview lasting ten minutes or so they did not have time to do justice to themselves. By this method they would be interviewed in all for about one and a quarter hours. We tried to reassure them as much as possible by saying that we appreciated that most people found any interview an ordeal, and if they were not used to discussions they might find this kind particularly difficult. Their final assessment, however, would not depend on any one test alone. They were then asked to discuss as freely as possible the topic printed on a slip of paper given to each candidate.

The Topic

We have experimented with the kind of subject the candidates are asked to discuss. To give everybody a fair chance, we avoided subjects about which the knowledge and experience of candates might vary; and controversial subjects were excluded because we did not want to test ability to debate or argue. "The qualities necessary in a doctor" was used for some time, but we found this subject too general to be discriminating. Such topics as "The results of an experiment cannot be wrong" and "In science the primary duty of ideas is to be useful and interesting even more than to be true" *were stimulating though difficult.* They seemed to have the following advantages:

(1) It is probable that they are equally unfamiliar to most candidates so none would have an unfair advantage.

(2) They invoke the kinds of thinking we wanted to test, and allow discrimination between candidates.

(3) We were developing a method of teaching certain *scientific skills by group discussion* (Johnson 1950, 1952), and we could call on our experience of the ways students talk about such problems to help to assess the candidates.

The Behaviour of the Assessors

This is of great importance in any interview, and it was our aim to make the candidates feel as much at ease as possible, so that they could concentrate on the problem. They would almost certainly feel themselves as competitors, so we maintained a neutral position, showing no approval or disapproval, agreement or disagreement, *but at the same time trying* not to appear aloof or unsympathetic. We found it best to say very little in the early stages of the discussion in order to give candidates the opportunity of taking the initiative. Later we would take a more active part, if necessary trying to draw out any specially silent people, or confirming the impressions we had already formed. Finally, with the aim of relieving any feeling of frustration which the participants might have at grappling with such a difficult subject, we would attempt to clarify confusions, point out discrepancies between statements, or reconcile different views, and show how the discussion had been concerned with problems of very fundamental scientific importance. With rare exceptions the assessors found the discussions extraordinarily interesting.

There is obviously a need to experiment with the part that the assessors play in group interviews. The experience of those who have studied some of the complex interactions between participants in interviews can be extremely useful in helping one to understand some of the difficulties involved (Oldfield 1941, Rogers 1951).

Assessing the Candidates

First, the two assessors separately graded the candidates on the five-point scale (Aitken and Johnson 1952). They then discussed them, and agreed on the grade which was to be presented at the final meeting of selectors. The assessment is based on the observation of a complicated piece of social and intellectual behaviour, certain aspects of which can be considered separately.

Adjustment to a difficult situation.—The topics are difficult, and the whole situation in which the candidate finds himself is very trying, but a doctor's life is, after all, not one of uninterrupted ease, and it seems legitimate to assess candidates on their ability to cope with some kinds of stress.

A few candidates, in spite of encouragement, say so little during the 50-minute interview that any assessment of them is bound to be unreliable. Nevertheless, it is probably fair to assume that such a candidate has less claim to a place than one who can cope satisfactorily with the same situation; and in fact none of the four candidates who made no contribution to the discussion did well in the individual interviews.

But candidates who say little do not necessarily get a low assessment. Some have an extraordinary capacity for taking in what is going on, and after saying nothing for a long time will suddenly take charge of the discussion, clarifying and summarising what has been said. Others seem to ruminate apart, and then produce a new idea which leads the discussion into different channels. It is scarcely necessary to add that those who say a lot do not always get a high assessment.

Personal relations.—Some candidates seem to establish good relations with others easily, while some are aggressive or overcompliant; some are consistently helpful and sympathetic, others carping and destructive; some seem to be generally liked, even if they are obviously more competent than the rest, and others seem to put everybody's back up. A very few seem to be uncoöperative, or at least not very tactful—e.g., those who appear bored and listless, or those who persistently talk too much so that others do not get a chance. Social factors have to be taken into account in assessing the ease of personal relationships, and the information supplied on the application form and referee's report are helpful here. We are attempting to assess what Dr. C. F. Harris (1951) described as the "capacity to fit in with and to surmount obstacles in his environment . . . the capacity of a public school boy to live down the worst pitfalls of a public school education, or of a miner's son to remain on equal terms with those coming from an entirely different home background."

Understanding other people.—Some candidates listen attentively to what others say and seem to understand easily; others ignore, override, or misunderstand them.

Ability to understand the topic.—Some people often refer to the typed slip, and try to make sure they are discussing the subject given; others read the statement inaccurately and may fail to discuss it properly.

For instance, it is common for at least one person in each group to talk as though the topic "In science the primary duty of ideas is to be useful and interesting even more than to be true" was in fact "The primary duty of science is to be useful"—i.e., to provide equipment and material of practical use in everyday life. Again, the statement "Observation is a process of selection or discrimination—a process of selecting and discarding from the sum total of presenting objects" is sometimes misinterpreted, and discussed as if it read "Selection is a process of observation . . ." and as if it was concerned with the selection of medical students.

Mistakes such as this (and indeed all the statements made) must of course be evaluated in their context. If the first person who speaks makes such a mistake he may be excused on the ground that perhaps he feels impelled to say something and does not allow himself time to consider; but a candidate who makes the same mistake late in the discussion or who persists in making it even when it has been pointed out to him is less easily excused.

The quality of the contributions to the discussion.—The points looked for here include clarity of expression; recognition of sources of confusion—e.g., that caused by using the same word in different senses; comparing and contrasting various viewpoints; bringing up new points; and reviewing the discussion at intervals. The discussion lasts long enough for us to see that some candidates are able to reconsider, and if necessary to modify, their own opinions, while others seem to be less receptive to ideas which are new to them, and tend to repeat without modification things they have said before.

CONCLUSIONS

The ideal candidate is one who adjusts himself satisfactorily to the situation; gets on reasonably well with everyone else; listens to what others say; expresses himself clearly; talks sensibly; has a good grasp of the implications of the topic and of the matter of the discussion; and is able to re-evaluate his opinions in the light of what is said. This may seem a tall order, but of the 204 candidates interviewed this year, 19 were assessed as A (very good) and 64 as B (good). Candidates considered good are of many different kinds, showing various combinations of the desirable qualities. Indeed, the group interview seems to bring out the infinite diversity of candidates.

The kind of qualities which can be assessed by this method, the nature of the topic used, and the manner in which the discussion is conducted all need further experimental investigation. The remark of Oldfield (1941) about the individual interview is also true of the group interview: "At this stage of our knowledge the prime object of discussion must be to stimulate thought. Those whose business it is to conduct interviews could render invaluable service to their art if they would reflect upon the methods they use, give expression to their views, and try to perceive clearly the psychological implications and conditions of what comes to their notice."

The work reported here was done during the tenure of a grant from the Rockefeller Foundation.

FILARIASIS IN THE PACIFIC

FROM A CORRESPONDENT

FILARIASIS is widespread in Polynesia and is indeed the main bar to progress in these beautiful and fertile islands. The International South Pacific Commission set up in 1949,[1] which now has its headquarters in Naumea, New Caledonia, is concerned, among other things, with suppression of the disease. The parasite responsible is a non-periodic microfilaria, whose adult form is now known as *Wuchereria pacifica*, and it is transmitted by the day-biting mosquito, *Aëdes pseudoscutellaris* (probably in reality *A. polynesiensis* Marks).

Since 1948, American workers have been active in the study of Polynesian filariasis, especially in Samoa and Tahiti, and some results of their researches have now been published. A group of entomologists, parasitologists, and pathologists from the University of California has been working in close association with members of the French Medical Research Institute at Papeete, the capital of Tahiti.[2] In this historic island the proportion of inhabitants harbouring microfilariæ in their blood and showing clinical signs of the disease is higher than it is in any other Pacific island yet investigated. Among the large number of people examined, no male over the age of 50 was free from signs of filariasis. (In all parts of Tahiti the proportion of males harbouring microfilariæ was higher than the proportion of females, which points to some discrepancy in exposure to, and acquisition of, the primary infection.)

Following the example of Fiji, an all-out effort is being made with the eventual aim of eradicating the main mosquito vector, *A. pseudoscutellaris* (*polynesiensis*), from the island of Tahiti and its satellite Maiao (approximately 60 miles west).[2]

To assess the prevalence of filariasis, studies were undertaken in nine areas, of which eight were on the main island and one on Maiao. The indices chosen to determine the ultimate effect of control measures were based on the average number of microfilariæ per 20 c.mm. of blood per person, the proportion of persons whose blood contained microfilariæ, the number of attacks of lymphangitis or filarial fever per person in the area, and the density of *A. pseudoscutellaris* (*polynesiensis*) in the larval and adult stages as well as the rate of filarial infection in wild-caught mosquitoes. A census of the adult mosquito population was made by means of observations at three "resting" and three "biting" stations in each of the nine areas; at the former collections were made between 8 and 9 A.M., and at the latter between 1 and 2 P.M. Here the captured mosquitoes were dissected to ascertain whether they were infected. A comparison between the mosquito populations and the average number of infected larvæ found in them, before and during the experiment, provided valuable information about differences in transmission-rates.

In the nine areas the average total percentage of the population with microfilariæ in the blood before the inauguration of control measures was 32·2. (In one area in Tahiti it was 58·3, while in Maiao it was 21·1.) One area (with a percentage of 38·6) was retained as a control, while in the other eight the measures varied. In some of them sanitation alone was employed; in others sanitation plus destruction of mosquitoes with D.D.T. In some the population were given 'Hetrazan' (2 mg. per kg. body-weight three times daily for seven days); and in others both hetrazan and insecticide were used. Sanitary measures were directed to mosquito breeding-places, with the object of draining or destroying them. Anti-mosquito measures consisted mainly in spraying the interior as well as the exterior of houses with 5% D.D.T. emulsion in water every three months while all vegetation within thirty yards was treated with 1% of this insecticide.

Of the nine species of mosquito, *A. pseudoscutellaris* (*polynesiensis*) and *Culex fatigans* were the most abundant. The former was found breeding in a great variety of places, the most important being coconuts, especially when rat-eaten. It seems that neither sanitation alone, nor D.D.T. alone, reduces the numbers of this aëdes as effectively as it reduces the numbers of other species. It was found, however, that where the population of an area had been treated with hetrazan the proportion of mosquitoes with infective filaria larvæ was reduced—in one area from 10 to 0·6% in a year.

The percentage of people with microfilariæ was estimated before, at six, and again at twelve months after treatment had been instituted. In each of the four areas in which hetrazan was administered, the percentage of positives fell appreciably; but a comparison of those positive before and after treatment does not show the effect of the drug so clearly as does a comparison of the actual numbers of microfilariæ per 20 c.mm. of blood, which on the average were less than 10% of the original number. It is particularly difficult to assess the influence of the drug on the frequency of attacks of lymphangitis, but in general it may be stated that the effect on other filarial manifestations was disappointing. The investigators feel that their data do not yet permit of statistically significant conclusions regarding the absolute superiority of any single method. In the attempt to formulate a programme for the control of filariasis which must extend over a long period, many points had to be taken into consideration. Necessarily it will require years of further study in order to determine how far the clinical manifestations of filariasis are reduced by the measures adopted.

A good deal of evidence on the transmission of filariasis outside the villages has been collected by Jachowski and Otto[3] in American Samoa. There a survey of ten villages was undertaken, and four collecting-stations were established for each village at varying distances from the open green or *malae* and at various distances in the bush leading to the banana or coconut plantations. Collections made within a period of $1^1/_2$ hours on a single afternoon yielded over 2000 mosquitoes which were then dissected for larvæ of *W. bancrofti*. In the bush itself the frequency of infected mosquitoes seemed to be related to the amount of native traffic, none being found in the areas devoid of human beings. The index of transmission was obtained by multiplying the density by the proportion of mosquitoes infected. From this it appears that mosquitoes in the houses and in the open *malaes* are of little importance compared to those in nearby bush or in houses close to it. The index is very high 175–275 yards from the centre of the villages. It thus appears that, in Samoa at least, one hour spent in the bush offers greater opportunities for infection than twenty-three hours spent in the village.

The age and sex distribution of microfilaræmia in Samoans added to the habits of the people, or to the biting habits of *A. pseudoscutellaris* (*polynesiensis*), support the conception of non-domestic transmission which is common also to *W. malayi*. Consequently in American Samoa residual spraying of native houses cannot be expected to be useful. The attack on the mosquito must be made in the bush. The same appears to be true for Tahiti and other islands of the Pacific where the non-periodic microfilaria is found.

Reconstruction

PAYMENT FOR MEDICINES IN AUSTRALIA

M. JOYCE DAMPNEY
B.A. Oxfd, M.A. Melb.
FORMERLY DOMINIONS SCHOLAR OF THE GOLDSMITHS' COMPANY, LONDON

It has become a political necessity to safeguard national finance from excessive expenditure on drugs. Three methods are open to a government. It can make a charge on all medicines (probably a small sum payable on every prescription); it can standardise prescriptions by means of a formulary; or it can say that only certain selected drugs will be supplied without charge. The first method has lately been introduced in Great Britain by the shilling charge on prescriptions. The second method was proposed in Australia in 1944, but the restriction of the doctor's freedom to prescribe evoked an opposition strong enough to prevent adoption of the scheme. The third method was introduced in Australia in 1950 and has operated smoothly.

THE AUSTRALIAN EXPERIMENT

In 1950, under the Pharmaceutical Benefits Act, a limited service of pharmaceutical benefits was introduced in Australia which incorporated proposals put forward by the British Medical Association in Australia. They believed that the financial burden of medicines to the individual could be eased if the government paid for costly drugs. They therefore suggested that a limited number of "life-saving and disease-preventing" drugs should be provided without charge to the patient. By Commonwealth government regulation a list of these free drugs was issued, in which there were no compounds. At first the list contained 139 items, and by March, 1951, there were 185 items. The cost of the Pharmaceutical Benefits Scheme in 1951–52, the first full year of the scheme, was £7,327,400. Of this amount £6,700,000 was paid to chemists for 6,500,000 prescriptions. In the present year (beginning July 1) the expenditure for one month came to £496,900 for 523,000 prescriptions, an average price of 19s. per prescription. The total cost includes payments to hospitals, bush nursing-centres, flying-doctor service, and those practitioners who do their own dispensing.

In 1951 the Pensioners' Medical Service was introduced which allows for all persons in receipt of an old age, invalid, or widow's pension, a Service pension under the Repatriation Act, or an allowance under the Tuberculosis Act, or their dependants, to receive compounded medicines as a charge on the Commonwealth government. The drugs offered under this service are those drugs appearing in the *British Pharmacopœia*, and proprietary preparations are not included.

The payments to chemists for pensioners amounted to £357,600 during 1951–52 and covered some 1,600,000 prescriptions. (This is only eleven months' expenditure because prescriptions dispensed in one month are paid by the Commonwealth government in the following month, and the scheme began on July 2, 1951.)

Prescriptions in Australia may therefore be issued under two Acts or supplied privately; and the three methods of issue are kept separate. The organisation has worked smoothly in practice and with general coöperation. At the same time, costs have tended to exceed estimates, largely because new and expensive drugs have been introduced. About a third of the prescriptions dispensed by chemists each year are paid by the Commonwealth government under the two public schemes.

Soon after the schemes began it was evident that excessive quantities of certain drugs were being prescribed, particularly the antibiotics. Also the government was faced with the need to save dollars—some drugs were supplied from dollar areas only—and to start a stockpile of drugs which might become scarce. Accordingly a measure of control was introduced on the doctor's freedom to prescribe.

At first in 1950 the doctor who wished to prescribe streptomycin or chloramphenicol for one of his patients had to write: "I certify that in my opinion there is no other drug available which would be equally effective in this case." Nearly three months later it was decided that the doctor could only write such a prescription after he had received a numbered authority from the director-general of health or his delegate. In each State the Commonwealth department of health operates a 24-hour service to respond to calls from doctors on the telephone and by telegraph. The minister of health is empowered to declare by regulation that a certain drug may only be prescribed in the treatment of a disease specified by him.

DISCUSSION

Unnecessary prescribing is a subtle form of abuse, seldom entirely conscious, and under a scheme such as the Australian one a doctor may overlook the fact that the free list is costly to the National Exchequer and prescribe in a way likely to save his patients' pockets. Thus there are times—and cases of mild infection may perhaps serve as an example—when the practitioner may select the more expensive free drugs in preference to simpler and cheaper drugs for which his patients must pay. On a large scale—and Great Britain has a population five times as great as that in Australia—such habits might well make the limitation of pharmaceutical benefits to a restricted list more expensive than a small flat-rate charge on all drugs. On the other hand, the introduction of a small payment on every prescription in Britain makes it difficult to avoid individual hardship, and informed opinion in Britain has shown interest in the Australian scheme. Lord Moran,[1] who opposed the flat-rate charge on every prescription, suggested that a distinction should be made between essential and non-essential drugs, and only the essential drugs issued free of charge. Yet to make such a distinction might prove difficult in practice, since drugs are prescribed for people, and it is people, rather than drugs, that have an essential need or a less essential need. To take an example: a man in employment who has pneumonia and is absent from his work for a month or so, remaining on full or half salary and in receipt of sick benefit, would probably receive free treatment with an antibiotic (considered essential). On the other hand a man with a chronic disease, such as disseminated sclerosis, who is unable to work, might be asked to pay for sleeping drugs, digestive mixtures, and other palliatives (considered non-essential) which he needs from time to time.

By legislation the State may proclaim one group of drugs as free and another group as not free, or may impose a flat-rate charge on prescriptions; but at best either scheme is clumsy and unfair in practice, and irksome to doctor and patient alike. One can only conclude that in the long run the best way of limiting the cost of prescription is through the medical profession. Only the doctor can educate the inconsiderate and ignorant patient, and only the doctor can decide when a drug is necessary and when a patient should be asked to make a small purchase at the chemist's shop instead of claiming a prescription.

In England Now

A Running Commentary by Peripatetic Correspondents

Sir Heneage Ogilvie last week must have pricked the consciences of many of us consultants. I know ever since I became a consultant physician in the eyes of the National Health Service, the terminology has worried me. This is the sort of thing that happens when perhaps one is invited out to dine.

Guest: "Oh, I hear you are a doctor. How wonderful! *Are you in general practice?*"

Self: "No, I work in a hospital."

Guest: "*You are a specialist, then?*"

Self (guiltily): "Well, I suppose I am officially."

Guest: "What do you specialise in? Are you a heart specialist or a nerve specialist, or what?"

Self (embarrassed): "I don't really specialise in anything. I do general medicine."

Guest (suspiciously): "I see."

Second Guest (whose wife's second cousin is a doctor): "I know, you're a house-physician."

Self: "No. I was one many years ago, but not now."

Hostess (coming to the rescue): "You're a consultant, aren't you?"

Self (miserably—with memories of the grand old men who taught us in our medical schools long ago): "According to the regulations, I'm of consultant status but whether I'm a real consultant, I don't know."

Silence, while all the guests take this in and become convinced you are lying and have been struck off the register for an illegal abortion or for signing a wrong certificate.

I wish Sir Heneage could devise a term for us which is not too insulting. Meanwhile, perhaps Mr. Stephen Potter could tell us how to cope with the situation, and direct the attention of the famous school at Yeovil to our predicament. How does Odoreida get out of it?

* * *

I got my fellowship and my allotment on the same day; I had waited a long time for both, but there was no doubt which gave me the greater pleasure. The allotment has waxed fat; never such tasty asparagus, such succulent strawberries and tomatoes to strain at the leash of their staking. All this, of course, is a matter of pride, but for the heaviest crop of all I can claim no merit. Our *Coprinus comatus* have had a long season and seem still to be coming on. Spinach marches proudly in ordered rank and even the marrows are marshalled, but you never know where coprinus will be tomorrow; perhaps between the bean rows, or round the rhubarb, or inside and outside the cold frame. Its range extends from one plot to the west of mine to two to the east—from all of which I harvest them to the doubting wonder of the owners. Before I bought the twin slim volumes, *Edible Fungi* and *Poisonous Fungi*, I knew coprinus only as the Inky Cap, nor thought of using it for anything but the blacking of leather shoes. Even after careful identification from legend and coloured plate I cooked and ate the first takings with terror in my heart, and for three days I ate them alone. The family hastened to inspect me each morning, but my health remained excellent. Then we had a Danish guest who ate them gladly, and they were won over; so now we all eat them every day. The taste of coprinus is like that of the field mushroom but perhaps a little stronger; they fry well, are delicious steamed and served with butter, and make an excellent sauce. Perhaps next year my allotment will yield *Morchella esculenta* or even *Cantharellus cibarius*. But by then the other allotment-holders may have been given the books for Christmas and be anxious to gather their own free-given crops! Till then we shall gorge ourselves and hope that the bomb-debris that underlies our tilth will burgeon as richly every year.

* * *

Our recent attempt at the best of three falls with one of the august bodies that reside behind Southampton Row has given us a respect for the London taxidriver's powers of observation and diagnosis. Inwardly trembling, but outwardly "with merry oath and laughter and a smile upon our lips," we stepped into a taxi and asked for Queen Square. Instantly penetrating the façade, he asked "Examination 'All?"

* * *

The boy who debunked Harvey in "News from School" on Oct. 18 is a lad after my own heart. I believe that if a group of 12-year-old modern schoolboys were presented with the anatomical facts as Vesalius knew them, at least half the boys would discover the circulation of the blood in five minutes. Why then, you may ask, did not Vesalius anticipate Harvey? When you look at Vesalius's illustrations of the heart you wonder how he could have accepted Galen's teaching that the blood passed from one ventricle to the other through pores in the septum. But, after admitting he could not find the pores, he let the matter drop. There are those who say he really did discover the true function of the valves but he was afraid that publication of his opinion might invoke religious persecution. This is pretty thin. I think the true answer is to be found in "climate of opinion." Brilliant anatomist though he was, Vesalius never escaped *from* the galenical climate. Harvey escaped—probably by chance, but possibly because he was a stranger. You can visualise him, awkward, mulish, and cranky, among the elegant Italians. He never really belonged, so he did not have so far to go.

That explains Harvey, because, the more you think of it, there was nothing really *in* the circulation—nothing that Macaulay's schoolgirl couldn't figure out in a few hours. And now in return for my explanation, can you tell me which philosopher, psychologist, or scientist, writing about 1911, invented the phrase "climate of opinion"?

* * *

The general practitioner's life is not made easier by the unceasing postal bombardment with bits of blotting-paper—varied with high-grade [illegible] to impress on him the virtues of [illegible]. There is, of course, no positive harm in this [illegible]table series, and no doubt when they are taken to school by the doctor's children the status of the family is enhanced. But it is a sobering thought that these snappy pharmacological messages often occupy most of the time which a busy practitioner can spare for professional reading. Is it fair to those who taught him his job in the medical school and hospital that he should be thus deserted? We live in an age that has seen the revival of the "News Letter." Topical, concise, and informative, it often fulfils a real need for the busy man who is putting all he's got into his job. Isn't it time we had a news letter in therapeutics—perhaps on the lines of the *Army Medical Department Bulletin* that so many isolated M.O.s found useful in the late war?

And then, what fun it would be spotting the authors of these miniature annotations: nothing longer than 100 words—what a training for aspiring after-dinner speakers. Here the limpid prose of a Robert Platt, there the authoritative dicta of a Henry Cohen, and that tell-tale phrase pathognomonic of an Englishman exiled in Scotland. Are we on the threshold of a new medical literature?

* * *

International kudology needs a clear head and a quick tongue. Before going to the States I was warned that no-one would be introduced to me as plain Professor unless for some unfortunate reason he had no doctorate of any kind. And so it turned out: it was an embarrassing moment meeting him. But there came another day when I had to confess that I also wasn't a doctor. Hoping to give the right impression, I went on to explain that in England a bachelor's degree was all that was required for qualification, and that there were a few very eminent men who were satisfied with the simple letters M.B., F.R.S. "Oh!" came the reply, "we never put membership of societies after our names."

* * *

A NEW DIALOGUE

Medico: Good morning, Socrates.

Socrates: Good morning, Medico. Did I see you emerging from the hospital just now?

M.: You did, Socrates.

S.: And what have you been doing there?

M.: Removing the tonsils of a dozen children.

S.: For the reason, I suppose, that they will be better without their tonsils than with them?

M.: Assuredly.

S.: Is every man therefore necessarily better without his tonsils than with them?

M.: How not?

S.: But I am asking you, Medico, whether you think that every man should be deprived of his tonsils at birth or at some other time.

M.: No, Socrates, not every man, for then there would be no end to the removing of tonsils.

S.: I understand then that you have to select some tonsils *rather than others for removal?*

M.: Certainly.

S.: Presumably those children with bad tonsils will be selected for operation rather than those with less bad ones.

M.: How right you are, Socrates!

S.: *It follows therefore that it is better to have bad tonsils* than good ones.

M.: By what process of reasoning, Socrates, have you reached that conclusion?

S.: For, O wonderful one, it is clear that those people with bad tonsils will be deprived of them, while those with less bad ones will be left with theirs.

M.: I suppose so.

S.: And what do you do with the children after the operation?

M.: They are put into several beds in one ward where they are cared for by the nurse until the wounds are healed.

S.: There are then, or might be, O Medico, twelve children in one ward?

M.: You say true things, Socrates.

S.: And have you read the instructions of the Governing Body about the number of cubic feet to be allowed to each patient?

M.: I am afraid that I have not.

S.: You surprise me, Medico. Surely it is your duty to read the regulations of the people set to govern you?

M.: I am a surgeon, Socrates. I am not an administrator.

S.: Indeed, Medico? But you would agree that the regulations are drawn up so that good should be done to patients rather than harm?

M.: I couldn't agree more, Socrates.

S.: Then if a sufficient number of cubic feet is not allowed to each child, more harm may eventuate than good?

M.: Perhaps.

S.: But surely, my good man, you must see this. Take horses for example: are not the best trained horses the ones allotted the most stable room?

M.: Yes.

S.: And the same would apply to bees, I suppose? Surely the bees with the optimum hivage area are the best cared for?

M.: I get you, Socrates.

S.: And does not the same principle apply to youths training at the Palæstra, criminals in prisons, badgers, and swallows and nightingales in their nests?

M.: I expect so.

S.: But listen, my good friend. I am speaking of facts and not of expectations. Surely you would not wish the human race to be *less well treated than animals*?

M.: Of course not.

S.: To return to horses, therefore—

M.: Look here, Socrates, I am a surgeon. You should tell other doctors these facts: see, they are all coming from the staff room yonder. But while I am with you, O *best* of men, tell me how I may best be enabled to perform my tonsil operations with a view to doing the most good possible to my patients.

S.: I would gladly do *so, Medico, but unfortunately* I have to come up before the Thirty in a few minutes: they are proposing to accuse me of corrupting the Youth's health by evading the regulations of the Governing Body and overcrowding the hospitals. . . .

Letters to the Editor

SPECIALISTS AND THEIR QUALIFICATIONS

SIR,—Sir Harold Himsworth *from a position* of authority stresses the dangers to research of too rigid and fixed boundaries between organised subdivisions of knowledge. On a question of terminology, may I however suggest that the term "stratification" is merely the same thing. I raise the question, not just as a verbal quibble, but because there is something of a different character which may legitimately be called stratification, and which is also a danger to research by interfering with the free interchange of ideas: I refer to stratification according to the position of individuals in the hierarchy of their group, a phenomenon particularly liable to occur in clinical medicine. It is my strong impression that both dangers are less marked in American than in British medicine, and that our American colleagues are both more bold than we are in following a clue outside their own specialised departments of knowledge, and better at mixing on terms of intellectual equality irrespective of hierarchical status within the group. Finally, is it really too late to reverse the present trend towards an excess of "precisely *prescribed requirements for the training of consultants* and specialists," and to recognise that too rigid definition of temporary boundaries of convenience, and consequently of qualifications for entering within those boundaries, may in the long run be harmful to progress?

London, W.1. DAVID PATEY.

FUTURE OF THE OCCUPATIONAL HEALTH SERVICES

SIR,—Those who criticise the report of the Dale Committee do so for two reasons: first, they have not understood its terms of reference; and, secondly, the critics assume that planning as such is a good thing.

The first misapprehension is easily corrected by those who take trouble to obtain the report and read it, when they will find the committee's terms of reference were very largely confined to conservation of man-power. May I recall that the committee proclaimed the importance of industrial health services. This is more than many of its critics have done. In the difficult political circumstances at the time of the committee's appointment and during its deliberations, this cannot, in fairness, be called timid. Even to have disposed of the implications implicit in the Prime Minister's ban on developments in industrial health services pending the committee's report, is a valuable achievement.

The onus of proof that planning is good should lie on those who wish to plan. The standard of British practice in industrial health is the highest in the world. That is no reason for not trying to make it better, but it is a reason for caution. Without exception all legislation planned in vacuo has been a failure. To hamper industry (meaning all forms of work) with unsatisfactory legislation is too serious. The usual argument used by planners is "what about the small factories?" I have not heard a logical development of the argument beyond this point. Supposing the state of small factories is bad (which I do not accept), can it be improved by direct action of doctors? That is the crux of the matter. Maybe stronger enforcement of stricter *minimum* standards is needed; but that is a matter of legislation and inspection, not of medical services.

Planners must meet the following difficulties:

1. In the British tradition employers are responsible for the health, safety, and welfare of their workers. Sanctions and duties are placed by law on employers and workers; this being so, they must be free to seek advice from doctors whom they trust and of their own choice. This advice will be the

more readily accepted if it is an integral part of management. To provide this advice is the primary function of industrial health services. In spite of much political exhortation, the interests of employer and employee are the same in this matter.

2. Enforcement (not vague supervision) of minimum standards must be uniform throughout the country if differences between different parts, as between Lancashire and Japan, are not to arise. Unless the relationship between the central government and local authorities is to be profoundly altered, enforcement by the servants of local authorities (e.g., medical officers of health) is not acceptable.

3. Medical examinations (except for strictly limited objectives, such as a few toxic hazards) have, in modern circumstances, little bearing on health. Uncritical recommendations for widespread medical examinations as panaceas for all ills are too common. Since the school health service now sends young persons from school either in excellent health or with their defects known and categorised, even the appointed factory doctor's examination of young persons is of very doubtful utility. What other function is there for doctors, not part of the managerial team, to perform unless it be inspection to see that minimum standards are observed?

4. Very few doctors have the requisite knowledge and skill to give advice of the nature required by employers and workers. Vague generalisations will quickly bring medical advice into disrepute. How are the planners going to educate medical officers of health and others who wish to bring occupational medical services within their grasp?

Let me be frank. The Dale Committee's report undoubtedly disappointed many. To say that evolution is better than planning is unpopular. Evolution does not lend itself to quick paper empires. Too many persons think that industrial (or occupational) health is primarily a medical matter. To build up a large superstructure of doctors around industry would only place a useless and needless burden of bureaucracy and mediocrity on men and women at work. In the end, even the National Health Service depends on the efforts of these men and women. Accurate information, as opposed to theories and dogmatic summaries, is what is wanted. When this has been obtained, then and then only may action be taken with safety. I will forecast that action based on knowledge will be toward a small, highly skilled cadre of doctors rather than toward unwieldy and untrained regiments. My criticism of Government departments is not that they have not agreed—for they have nothing to agree on—but that one or all of them have not initiated surveys. Perhaps the coördinating committee recommended in the Dale report, if and when appointed, would do this.

Lest anyone should reply that this letter is special pleading, let me declare my interest. I was a member of the Dale Committee.

Southwell, Notts. T. A. LLOYD DAVIES.

SIR,—Your championship of occupational health is indeed welcome to all of us engaged in this field. Your contributors and your leading article (Oct. 11), however, seem to the less vocal of us to miss one essential point. The subject is treated as if it were a "service" which can be imposed from above by legislation, and quite logically the argument goes on to suggest that the answer lies with the Ministries.

The answer really lies with doctors themselves. The whole medical profession almost automatically knows its way about the stresses and strains of family life, of the life of the diabetic and the tuberculous. There are very few doctors, however, who understand the stresses and strains of modern industrial life; and until more doctors are trained in elementary industrial administration, legislation and a "service" will simply operate in vitro. Nothing I have yet read satisfies me on the in-vivo end of the stick.

Radlett, Hertfordshire. P. PRINGLE.

RECURRENT POLIOMYELITIS

SIR,—During last year's epidemic of poliomyelitis in Milwaukee, which was the most severe in the city's history, there was an instance of recurrent poliomyelitis. 49 examples of second attacks of poliomyelitis have been published, but 17 of these are considered doubtful because the details are incomplete, because a long time elapsed between the acute disease and its diagnosis, or because some other disease or trauma complicated matters.

First Attack

A white male child, aged 8 months, was admitted to South View Isolation Hospital, Milwaukee, on Sept. 15, 1950, with a story of fever for 5 days and difficulty in moving his right leg. There was moderate neck rigidity and spasm of the back muscles. The right leg was flaccid, and the right foot was moving spontaneously. The patellar reflex was absent on the right, but the ankle-jerks were present. No symptoms of bulbar involvement were apparent.

Lumbar puncture yielded a clear, colourless fluid under normal pressure; it contained 90 cells per c.mm., 84% of which were lymphocytes.

A diagnosis of acute anterior poliomyelitis was made. The boy recovered satisfactorily and regained almost normal movement in the right leg.

Second Attack

On Aug. 16, 1951, at the age of 19 months, he was again admitted to this hospital. The previous day the child vomited and became irritable and feverish.

There was bilateral ptosis, most marked on the left, an inconstant right internal squint, definite neck rigidity, tenderness and spasm of the hamstrings, and tightness of the back muscles. Generalised tremor was present; and the right leg tended to rotate medially. The previous attack had caused a slight decrease in the length and diameter of the right leg.

Clear, colourless cerebrospinal fluid was withdrawn under normal pressure; there were 62 cells per c.mm., 83% of which were lymphocytes; sugar 62 mg., chlorides 691 mg., and protein 10 mg. per 100 ml., with no rise in the globulin.

By the second day in hospital the fever had subsided, and the child began to eat well and was much less irritable. He was discharged after 10 days, but the bilateral ptosis persisted.

Fischer and Stillerman[1] estimate a rate of recurrence of 2 per 1000 cases, Nelson and Green[2] 0·66 per 1000, and Bridge et al.[3] 2·7 per 1000. They feel their rate casts doubt on the existence of any significant clinical immunity following a single attack of the disease. At South View Isolation Hospital 2343 cases of acute poliomyelitis were treated between 1921 and 1951; so with 2 recurrent cases our recurrence-rate is 1·7 per 1000. In both of our cases bulbar poliomyelitis developed in the second attack, and both times the second attack occurred within a year of the first.[4]

Hoyne and Lipton[5] quote Trask et al.,[6] McAlpine,[7] and Steigman and Sabin[8] in support of their view that immunity in poliomyelitis is specific only for the strain of virus in the original attack. However, they also think that the immunity conferred may give protection for only a short time. Still[9] also supported the idea of "minimal duration of immunity." According to Toomey[10] it is easier to reinfect monkeys with a different rather than the same strain of virus.

If we agree that poliomyelitis can occur in a subclinical non-paralytic form, it is quite possible that the apparent rarity of recurrence is due to the difficulty of recognising mild attacks. Bridge[3] agrees that, until we are better

able to diagnose the mild forms of the disease, the possibility of a second attack might well be anticipated.

It has been estimated that the incidence of second attacks of poliomyelitis is nearly the same as that of recognised first attacks in the population at large.[1–3] The number of people developing clinical poliomyelitis for the first time forms about the same proportion of the general population as those who have a second attack do of the known poliomyelitis population.

However, it seems that in undoubted recurrences the virus does not attack the same level of the central nervous system as before. This may mean that immunity has been "fixed" at a certain level or portal of entry, and that involvement elsewhere is possible. But if different strains of virus attack different levels of the nervous system, this observation may support the view that immunity is specific for specific strains and not heterologous for all strains of poliomyelitis; or it may merely mean that "the fire will not catch on burned out wood."

ADDICTION TO BARBITURATES

SIR,—I have been caused considerable embarrassment with members of the profession and others, in regard to reports which have appeared in some daily newspapers to the effect that at a meeting of the North East Metropolitan Regional Hospital Board on Oct. 22 I stated that there were hundreds of thousands of barbiturate addicts in Britain and, secondly, that barbiturate drugs could be purchased without prescription from some chemists.

I made no such statements or similar statements either at the meeting referred to or at any other time.

North East Metropolitan Regional
Hospital Board, 11A, Portland
Place, London, W.1.

JAMES GRAHAM
Senior Administrative
Medical Officer.

OVERLOADING THE CIRCULATION

SIR,—The occasion often arises when an intravenous infusion has to be administered to a patient in need of fluid replacement. This in itself usually presents little difficulty. Yet as soon as continuity with the bloodstream is effected, there comes creeping into the medical mind the dreadful thought that the circulation may become overloaded. The fear of killing the patient is greater than the hope of curing him, and encourages prompt action to reduce the rate of flow to safe limits; and commonly the recipient then has to make do on meagre measures.

Surgeons—who only employ the stethoscope to listen to bowel sounds, or its rubber parts for cavity drainage—are especially apt to fear overinfusion. Physicians, on the other hand—providing they can overcome the mechanical difficulties of setting up a drip—are much more confident, owing no doubt to their assured ability to recognise circulatory distress.

Very many textbooks stress the danger of overloading the circulation and give the impression that this is common. Having given and seen given many hundreds of infusions, I am sure I have yet to see overloading of the circulation; and I am equally sure I have seen patients die for want of fluid, which was denied them by myself and other misguided persons.

Of the many colleagues who searched their minds to recall a case of overinfusion of a patient with normal heart and kidneys, only one could remember such a case—that of an infant who received a litre of normal saline in one hour. It is well known that when the heart and kidneys of the child or adult function normally any excess of water or salts can be disposed of at a prodigious rate. In diabetes mellitus the patient may void twenty or more pints of urine per day, and there are thirsty manual workers who could deal with as great a quantity in a shorter time.

Blood-transfusion presents a somewhat different problem, and calls for a much less liberal technique—particularly in cell restoration of the chronic anæmic patient, or in the transfusion of a patient with cardiac decompensation. Nevertheless, in the more common condition of acute blood loss the tendency still remains to administer blood too slowly and in too small a quantity. It is clinically obvious during operation that the normal patient benefits by having a greater quantity of blood transfused into the circulation than has escaped from it.

A modern revaluation of intravenous infusion and transfusion therapy based on clinical observation is surely called for.

Kingston Hospital, Surrey.

W. R. MURPHY.

THE HARROW ACCIDENT

SIR,—As I have been unable to obtain a complete list of all the doctors who rendered aid to those injured in the unfortunate train accident at Harrow and Wealdstone on Oct. 8, I should be grateful for the opportunity to send my sincere thanks to all of them through the medium of your journal.

I know the names of some of them of course, whilst others preferred to remain anonymous; but, in keeping with the highest traditions of the medical profession, all of them rendered such invaluable aid that it is impossible to estimate how many more lives would have been so tragically lost had it not been for the medical attention given to them either before or immediately after they were brought from the wreckage.

I should like each and every doctor concerned to accept my very sincere and grateful thanks.

London Midland Region,
Euston Station, N.W.1.

J. W. WATKINS
Chief Regional Officer.

REACTION TO PROCAINE

SIR,—In view of the reports in your columns of severe reactions to penicillin with and without procaine,[1] the following case may be of interest.

A man, aged 47, had complained of fibrositis of the right trapezius muscle. This had not responded to simple massage with liniment, and I decided to inject 'Novutox' (a solution of procaine hydrochloride 2% and adrenaline in Ringer's solution rendered "self-sterilising" with capryl-hydrocupreinotoxin hydrochloride). I gave him a deep intramuscular injection of barely 3 ml. of novutox. Almost at once he began to feel ill. I rather disregarded this, and after about 4–5 minutes I massaged the muscle quite vigorously. About 3 minutes later he appeared about to faint. He lost consciousness, and developed a generalised tonic spasm. He became completely pulseless, and regurgitated some of the stomach contents.

About 2 minutes later he took an odd breath or two as the spasm relaxed. After a further 2 minutes or so he began to breathe again deeply, his airway having been kept clear ever since the spasm developed.

Some half-hour later he regained consciousness, but for a further 2–3 hours he felt very ill. He was taken home, after walking to the car, $4\frac{1}{2}$ hours after the injection, and by next day was up and about.

I believe that this man, who had previously withstood injections of adrenaline for asthma, which used to trouble him in his younger days, is sensitive to procaine, though he had had local anæsthetics for occasional dental extractions. The effect of this sensitivity to procaine was increased by the massage I gave him after the injection, though I am as sure as one can be that I

did not inject into a blood-vessel. I used a no. 12 hypodermic needle. There was no local reaction at the site of the injection, even though I had first given some of the injection just beneath the dermis.

London, S.E.26. RONALD M. PENNY.

BRONCHIAL CARCINOMA

SIR,—Last week's letter from Dr. Hesling and Mr. Cruickshank draws attention to an important symptom of bronchial carcinoma insufficiently regarded. Here is the history of a patient recently in my care:

A year ago a man of 50 went to his general practitioner and said: "Doctor, I have a wheeze in my chest just *here*, which has recently appeared, and will not go away," and pointed to the upper part of his left chest. The doctor placed his stethoscope on the spot and, sure enough, heard there a rhonchus which persisted after coughing. There was no other symptom, no other sign. He promptly referred his patient to see a chest physician from a chest hospital. The rhonchus was still there. A full investigation was instituted. Chest radiographs were normal. Bronchoscopy was performed, and was negative. Finally a bronchogram was done, and reported as showing no abnormality; and the patient went home.

A year later he visited another hospital and was again examined radiographically. This time a growth of the anterior segment of the left upper lobe was manifest. It proved to be just operable; but the prognosis is poor, and in any case a year the worse. The previous bronchogram, on re-examination, showed perfect filling of the whole lung—save the anterior segment of the left upper lobe.

The lesson is simply this: a fixed rhonchus is pathognomonic of partial organic bronchial obstruction; and incomparably the commonest cause in a man of 50 is cancer.

London, W.1. GEOFFREY FLAVELL.

THE EMERGENCY OBSTETRICAL SERVICE

SIR,—Mr. Dewhurst is to be congratulated on his excellent review (Oct. 18) of the work of an obstetrical emergency service, and for emphasising several important points.

It has always amazed me to find that a doctor who tackles a difficult forceps delivery or breech extraction in domiciliary practice may hesitate to remove a placenta. Few teachings have done more harm than the one that manual removal is dangerous and only to be carried out as a last resort.

Mr. Dewhurst's condemnation of the continued misuse of pituitary extract is welcome. Surely this drug can have no place in obstetric practice, except possibly in a drip for the treatment of inertia: after delivery ergometrine has its virtues with none of its vices. Forceps delivery under chloroform anæsthesia, administration of pituitary extract, and repeated attempts to express the placenta is a shock-producing combination.

His recommendation that all patients with a history of previous postpartum hæmorrhage or retained placenta should be delivered in hospital is important. It is very disturbing to find the flying-squad being called to a patient who has been treated by it for profound postpartum shock in a previous labour. The risks in the "dangerous multigravida," and the desirability of her being delivered in hospital, are now generally realised: but it is still sometimes difficult to persuade these faithful mothers to come in.

Mr. Dewhurst rightly emphasises that a normal blood-pressure level need not be reached before the placenta is removed. The partly adherent placenta seems liable to produce shock; and if the patient's condition is improving with treatment, and open-ether anæsthesia with its supreme safety is used, the operation should not be deferred. Mr. Dewhurst mentions intravenous anæsthesia, but many anæsthetists are unwilling to use this unless an apparatus for giving oxygen is available.

There is one point, however, on which I must join issue with Mr. Dewhurst—and that is over the small amount of one or two bottles of blood which he regards as adequate for resuscitation. Although the mortality he reports is very low, considering the type of case treated, I wonder whether his results might have been better if larger amounts of blood had been given. The main difficulty here would appear to be the strain on supplies of Rh-negative blood, as unfortunately many of these patients have not been tested for their rhesus group. He does not mention plasma or plasma substitutes. It has always seemed to me unwise to run ice-cold blood rapidly into a shocked patient; and the rapid administration of dextran or 'Plasmosan' at the start of a transfusion is very valuable, and less likely to cause venospasm.

Maintaining an obstetrical emergency service in a populous area with many domiciliary deliveries throws a heavy strain on the obstetrical staff. I feel that the demands on a service and the amount of work it has to do can be greatly reduced if some of the points Mr. Dewhurst has emphasised are more generally appreciated.

Middlesbrough. BRYAN WILLIAMS.

DARK ADAPTATION FOR SCREENING

SIR,—During fluoroscopy sessions it sometimes happens that there are intervals between the screening of groups of patients when it is desirable to have some illumination, but when full dark adaptation must be preserved. I have found that two 60-watt bulbs, one coloured red and the other dark blue, burning together, give an adequate light for writing or reading, but do not disturb dark adaptation. I find that I can see the screen more clearly after having been in this light for a time than after having been in a room lit by a neon bulb, and that this method is more comfortable than wearing a dark-adaptation eyeshield with ordinary illumination; but these are subjective impressions which may not be confirmed. Others may like to try this form of lighting.

London, E.1. ALAN WATSON.

PNEUMA, PSYCHE, AND SOMA

SIR,—Dr. George Day (Oct. 11) says that "every layman is acquainted with well-authenticated stories of presumably healthy primitive men turning their faces to the wall and dying for no ascertainable organic cause, but just because a spell has been put on them." I have spent over forty years in various parts of the tropics but do not know of a single "well-authenticated" case of this kind.

Many years ago in the West Indies I investigated two cases of death which were supposed to be due to obeah spells; but there were "ascertainable organic causes" in both cases. One of the deceased was a man with pellagra: in the dementia of that disease he had turned his face to the wall and died, but the relatives were convinced that he had died of an obeah spell. I had experience of other cases in Africa.

Anyone who tries to investigate these stories of death from witchcraft or spells—they are much the same thing—will find that most of the related events took place at a distance in time or place—over the seas or beyond the hills.

I know of no part of the world where spells are recognised as causes of death either in mortality statistics or by the law; and assuredly if such a cause could be well authenticated there are many countries where recognition would be readily given, despite the difficult legal implications.

Dr. Day also appears to base much on a second proposition: "Every general practitioner is struck at some time or another by the way Darby will follow his Joan to the churchyard before the leaves have turned.' There may be something in this; but large numbers of Darbies and Joans survive their partners for a considerable time and no notice is taken of it. The odds are that a few Darbies will soon follow their Joans to the grave when both have reached the allotted span and this is more likely to receive comment and be remembered.

The progress of psychological medicine must be based on something more than popular beliefs. If such beliefs have foundations in fact these need to be supported by the evidence of experienced pathologists and statisticians.

Bantry, Eire. LUCIUS NICHOLLS.

UNSTICKING SYRINGES

SIR,—I have found a double-socketed needle invariably successful in forcing out adherent barrels of syringes that have become occluded with a large variety of agents ranging from clotted protein to crystalline deposits.

The needle is constructed simply by filing the bevel off the shaft of one hypodermic needle and cutting off the entire shaft from the head of another needle. The shaftless head is then attached to the free end of the unbevelled shaft of the first needle with silver solder.

The stuck syringe is freed by forcing fluid into it from another syringe through the special needle. The greater the difference of diameter between the stuck syringe and the freeing syringe, the easier it is to apply considerable pressure inside the stuck syringe. For this reason a long 1-ml. syringe is the most useful pressure-pump.

Tap water is quite sufficient for syringes stuck with clotted protein, while liquid paraffin may be used for a syringe stuck with crystalline deposits.

There is no danger of breaking the syringe, and slight pressure has freed all stuck syringes in this laboratory almost immediately.

Department of Experimental Medicine,
Cambridge. J. H. CORT.

RED CELLS IN ANIMALS

SIR,—In an annotation published in your issue of July 5 you discuss red cells in animals.

In cattle the red blood-cell count varies greatly not only between different animals but also in the same normal animal. The count may vary from 5 million to 13 million per c.mm. Changes occur regularly from day to day; and when plotted graphically these give a smooth curve. Furthermore, considerable changes occur in the course of a single day, and the red-cell count may vary by 2 million per c.mm. in a single hour.

With this rapid type of variation fall in the number of red cells is accompanied by reduction of the specific gravity of the plasma, and vice versa. Dried-weight estimations have shown that the reduced specific gravity is due to reduced content of solids. Plasma-volume estimations have shown that this reduction of solids is accompanied by an increase in volume of circulating plasma. The reduced red-cell count is, therefore, due to dilution of the plasma with fluid; and the volume of circulating erythrocytes in these cases is usually increased, not diminished.

When the plasma becomes diluted with fluid, a proportion of this passes into the red cells. This is easily demonstrated by mixing plasma of low specific gravity with cells separated from high-specific-gravity plasma: the specific gravity of the test plasma increases. Increase of fluid in the red-cells leads to increased mean corpuscular volume (M.C.V.), and the correlation between red-cell numbers and M.C.V. is easily explained. This also explains why the variation in the number of packed cells is less than that of the red-cell numbers.

During these changes total hæmoglobin varies remarkably little, because of variations in mean corpuscular hæmoglobin (M.C.H.); increased M.C.V. (with reduced red-cell count and reduced plasma specific gravity) is accompanied by increased M.C.H. I know that this will be considered heretical, but it undoubtedly occurs and can be demonstrated in another way. If plasma specific gravity is deducted from blood specific gravity, we get an index of red-cell weight. This shows a correlation with M.C.H., indicating that the increased hæmoglobin content is responsible for increasing the weight of the cells. On spectrographic examination, most cattle plasmas show traces of hæmoglobin. This was previously thought to be of traumatic origin. but possibly it may be due to physiological shedding by erythrocytes.

Intravenous injections of adrenaline into cattle often cause a fall of the red-cell count with the accompanying fall of plasma specific gravity. In other words the volume of the circulating blood is increased, but the fluid portion is increased to a greater extent than the cellular. The varying red-cell count in cattle, therefore, is connected with the control of water metabolism.

These findings have a wider significance than may at first sight be evident. In the first place, there would appear to be grounds for supposing that adaptation to hot climates and drought may be connected with control of water metabolism and may thus be reflected in the blood picture. In the second place, interference with the total volume of circulating plasma solids, not revealed by biochemical estimations, becomes apparent in diseases associated with anæmia.[1] The tissue degeneration of trypanosomiasis, malaria, and the kwashiorkor group of diseases can be explained much more reasonably by interference with deliveries of essential amino acids than by faulty delivery of oxygen. The anoxæmia of the "blue baby" does not cause tissue degeneration, whereas lack of methionine causes the typical centrilobular liver necrosis of trypanosomiasis. In trypanosomiasis we find further support for this view in vasodilatation and a much reduced circulation-time.

Some of these observations are to be described more fully elsewhere.

WITHDRAWAL OF TEACHING

SIR,—Your welcome leading article of Oct. 11 comes too late to influence the fate of the mobile film units of the Central Office of Information, but you did well to keep the issue alive. You rightly emphasise the value of the film as a teaching medium; this is still, I feel, largely unappreciated by medical teachers. The inconveniences which the new restrictions place in the way of the would-be user will further discourage medical teachers from adopting this powerful and convincing medium.

While not pretending that we can offer a substitute for the mobile film units, I would like to point out that the Central Council for Health Education does specialise in helping those engaged in medical and health education on questions of technique and media: and we would be glad to help any of your readers who may wish to consult us on this or other educational matters.

Central Council for Health Education,
Tavistock House, London, W.C.1. JOHN BURTON
Medical Director.

THE CORRECT SPELLING OF MEDICAL TERMS

SIR,—The editor of an important medical journal published in London (England) questioned my spelling of *fetus*. He refused to be interested in whether *fœtus* or *fetus* was etymologically the correct form, but said that if he printed *fetus* he would have a number of protests from his British readers complaining that he was adopting American spellings.

It is quite true that the spelling *fetus* is rarely used in British medical (or lay) literature. It is nevertheless the correct form. The *Shorter Oxford Dictionary* gives both *fœtus* and *fetus* but refers to the latter as the "better form"; it is from the Latin *fetus*.

Written English is built up by "common usage"—that is, in our view, common usage by British writers, most of whom are essentially conservative and resent change. They resent the liberties taken with their language by foreigners. For instance, they *like* diphthongs, tiresome though these may be to printers; with this point of view I am in complete agreement and I shall resist to the last ditch any movement for the general replacement of diphthongs by single vowels—the American practice. But when, etymologically, the foreigner is correct and we are wrong, it would seem that by adhering obstinately to a false diphthong we are weakening our case for maintaining our justifiable diphthongs in the face of contrary "common usage" by far more than half the English-writing world.

---

[1] Feldman, H. A., Murphy, F. D. *J. clin. Invest.* 1945, 24, 780.

It is admittedly about 250 years since *fœtus* first crept into English writing, but is it not time that it was gently eased out again?

Silchester. L. EVERARD NAPIER.

CURE OF TOBACCO-SMOKING

SIR,—As a doctor's wife, I should like to put forward the case for the ordinary smoker.

Smokers enjoy smoking. They do it openly and happily; they hand cigarettes to each other and most of them have a favourite tobacconist's shop where they exchange local gossip. They are not drug-addicts furtively stupefying themselves, but merry fellows who like having a straw in the mouth because they have a common nostalgia for the idleness of the yokel.

Doctors have too high a standard of human behaviour and forget that few people reach a more advanced mental age than 13 or 14 years. Ordinary people very much miss sucking sweets or chewing grasses or biting their nails.

Animals luckily do not have to change their habits with advancing years, so that we can still see an old cat spending spare time in washing its paws or sharpening its claws, or a dog in scratching or in wagging its tail, as they did in youth; but we humans are left with nothing to do with our hands or feet or teeth in those long stretches of idleness from which we all suffer when travelling or entertaining our friends. Gradually therefore the accepted consolation has become the cigarette, the substitute for paw-washing or tail-wagging or nail-biting—the ideal straw in the mouth.

London, W.1. B. W. EDWARDS.

SIR,—"Vouloir c'est pouvoir," quoted by Professor Alstead (Sept. 27), is by no means always true, I fear, of stopping smoking—even when the *vouloir* is backed by quite a lot of *savoir*!

Professor Russ's "smoker" of dummy cigarettes (Oct. 14) is indeed a rare bird. I have not seen or previously heard of one. With the important proviso, *where there is no consumption of tobacco,* I agree that "smoking" is a habit (on a par with gum-chewing).

I can assure Dr. Geiringer (Oct. 11) that life for me is not simple, though my thesis on tobacco-smoking is; but that surely does not make it less true. He asks what is the cause of mass (drug) addictions. The answer is, I *think*, mass psychological infection, which I discussed at some length. He also asks what is the balance of the good and evil effects of such (drug) addictions, and of tobacco-smoking in particular. There is no real balance of the good effects of disease. To addicts, in the case of the drug addictions, there seems to be, because addicts have fairly fixed delusions of beneficence about the effects of their drug.

Mr. Leacock (Oct. 11) accuses me of classifying smoking "among the vices of addiction." I stated that tobacco-smoking was a drug addiction—anyone who repeatedly gives himself a drug for non-medicinal purposes is clearly addicted to it—but not a vice. The phase of "gluttony" which may follow cessation of smoking usually passes after a few months. To recommend smoking as a remedy for obesity is a therapeutic crime.

The great increase in cancer of lung, and its proved association with tobacco-smoking, have been powerfully stated by Dr. Horace Joules (Oct. 18). Dramatic and tragic though cancer of lung is, the harm it causes is, in my view, much less in the aggregate than the insidious, protracted, and extremely widespread harm caused by tobacco-smoking. Pearl's table, to which I referred (Sept. 6), lends support to this view. There is clearly but *one* real solution to this problem—our prevention of tobacco-smoking.

Wallasey, Cheshire. LENNOX JOHNSTON.

SIR,—May I recall the origin of the *tobacco* plant as recorded in the *Koran*? Mahomet, while taking a stroll, found a serpent crushed under a fallen rock. He freed the serpent, which promptly rewarded him by biting his arm. Mahomet sucked his wound and spat on the ground; immediately there bloomed the tobacco plant, which contains both the venom of the serpent and also Mahomet's mercy.

Perhaps a form of agreement may thus be established between Dr. Lennox Johnston and his correspondents.

Puteaux, Seine, France. WILFRID JOULLIÉ.

FIRST-AID TREATMENT FOR NERVE-GAS POISONING

SIR,—It has been brought to my attention that anti-gas ointment will not be issued to Civil Defence Services, and hence the advice given about decontamination in the penultimate paragraphs of the memorandum entitled *Chief Characteristics of Nerve Gas with Notes on First-Aid Treatment*, published in the issue of Aug. 9, may not always be apposite.

In circumstances (e.g., in civil life) where adequate supplies of water are available and the contaminated skin can be speedily and thoroughly cleansed, washing is an effective means of decontamination for both nerve and mustard gases. If speedily applied there is, in fact, no better method for nerve gas. In Civil Defence practice any liquid contamination on the skin is speedily removed by wet swabs, and treatment is continued by thorough washing with plenty of water and soap.

Anti-gas ointment is, however, provided for Service personnel, since under active field service conditions adequate water-supplies for washing may not always be immediately available.

H. M. GARNER
Chief Scientist.

Ministry of Supply, London.

DANCKWERTS AWARD

SIR,—The many letters in medical journals concerning the Working Party Award have been most revealing, but it seems that one aspect has not been considered. Surely those who speak critically of "spoon-feeding young doctors" should consider more closely the difficulties of entering general practice today compared with before the late war.

Then, the young doctor could buy a practice and with it an established list of patients. Houses were easy to buy or to rent. Advances for purchase of both practice and house were not difficult to obtain. Having an established list, the young doctor was able through hard work to make himself appreciated by his patients and was therefore sure of recommendation to their friends. His practice grew by repute. Having risked his capital or pledged his future by mortgage he was reasonably sure of his bread and butter for many years ahead, even if his practice did not grow according to expectation.

Now, he must purchase a house, which will cost him as much as house and practice before the war. His capital is risked or his future mortgaged with no bread-and-butter list of patients to whom his care and hard work will recommend him. He is debarred from advertisement, and his initial practice allowance diminishes each year and ceases after three years.

There is no comparison in the risk. Formerly he had opportunity to show worth; now he has none. There may be in his neighbourhood several doctors with more than the maximum number of patients on their lists: patients will tend to go, not to an unknown unadvertised doctor, but by repute from one of the established doctors o another.

This, taken in conjunction with the fact that despite he award it is still more profitable to have an assistant han to take a partner, suggests that the undesired ncrease of a salaried service within general practice is ikely to continue.

Community Centre,
Farnham Road,
Slough, Bucks.
M. E. M. HERFORD.

INJECTION ROUTINE IN OPERATING-THEATRES

SIR,—The possibility of confusing gas cylinders or drugs in an operating-theatre is still a cause of concern, and may be a considerable danger to patients.

Some pharmaceutical firms issue various drugs in identical containers; and a few days ago a patient escaped an injection of a curariform drug, instead of the analgesic I had ordered, only by chance. If the ampoules had had easily distinguishable labels such a mistake would have been impossible, even in a busy and short-staffed hospital.

Lisbon.
LOPES SOARES.

*** The use of distinctive colours and labels for ampoules was discussed in our columns recently by Major-General W. E. R. Dimond and his colleagues.[1] They suggested that the risk of accidents could be reduced by colouring ampoules of certain injectable fluids used in operating-theatres. But there is an alternative view[2] that the only safeguard is to read and re-read the label, and that other devices for identification increase the danger of injecting the wrong substance. The question of gas cylinders has also been under consideration lately,[3] and a new code of colours is being introduced in this country.—ED. L.

THROMBOPHLEBITIS FOLLOWING INTRAVENOUS INFUSIONS

SIR,—In reply to the letter from Mr. Page and his colleagues (Oct. 18) it must be stated that in our study[4] the type of rubber tubing in the infusion sets was not controlled.

The investigation of thrombophlebitis in the surgical-unit wards began three years ago. At that time experience of a few latex sets was compared with experience of sets supplied by the North London Blood Transfusion Centre. The figures were small, but with the latex set the incidence of thrombophlebitis was no lower.

For the last two and a half years all investigations have been conducted with the standard North London Transfusion set. During this period the rubber tubing has been changed at least six times, and it was in fact changed three times during the investigation into the pH of the fluids. Despite these changes, since the introduction of the eight-hour time-limit two and a half years ago the incidence of thrombophlebitis has remained very constant.

The report by Handfield-Jones and Lewis[5] was published after the investigation into the pH of infusion fluids was completed. We propose to test the effects of different types of rubber tubing as the next step in our investigation.

With regard to the second point raised by Mr. Page and his colleagues, we found no difference in the incidence of thrombophlebitis with the fluid of pH either 5·6 or 6·05.

EFFECTS OF LEUCOTOMY

SIR,—Your annotation of Oct. 18 on Mrs. Petrie's book, *Personality and the Frontal Lobes*, praises the care and industry of the work, as well as the lucid presentation, but then goes on to say that "the results are disappointing because almost nothing was found that had not been described before by numerous observers."

Two comments seem relevant. In the first place, clinical observation in this field, as in many others, had resulted in a plethora of descriptions which embraced almost every trait and behaviour syndrome known to the dictionary; frequently the effects postulated by one worker were the explicit opposite to those postulated by another. Under these circumstances, it is very difficult to see how any study could succeed in unearthing behaviour not previously described; it is by producing *proof* where previously we only had contradictory *opinions* that Mrs. Petrie's study is outstanding.

In the second place, even if nothing more had been done than to quantify already existing clinical belief, does such a feat really deserve to be considered "disappointing"? To compare small things with great, it might with equal justice be said that Newton, in his *Principia Mathematica*, did nothing but confirm the phenomena which "had been described before by numerous observers"—i.e., the fact that unsupported bodies tend to fall to the ground. Science proceeds by proof and systematisation; it does not necessarily require for its advancement that its detailed findings should not, up to a point, have been anticipated by common sense and clinical observation.

The importance of such quantification is best shown by another finding of Mrs. Petrie, which is dismissed in the annotation in one sentence: "The variation of operative procedure had little and only quantitative influence on the test results." But to be able to follow experimentally such relatively small changes in operative procedure is in itself an important achievement, and to demonstrate that differences are quantitative rather than qualitative is something that could not have been done convincingly on the basis of clinical observation.

In addition, no mention is made of one of the most important findings in the book, which has since been confirmed—namely, that intellectual deterioration only occurs after posterior operation. This result alone, with all its implications regarding the localisation of functions in the brain, would suffice to show that the sentence quoted in the last paragraph does not give an accurate impression of the consequences of variation of operative procedure.

Institute of Psychiatry,
Maudsley Hospital, London, S.E.5.
H. J. EYSENCK.

BUTAZOLIDINE

SIR,—Having now used this drug in 237 cases of rheumatoid arthritis attending my outpatient clinics, I am still greatly impressed by its efficacy. I have used it alone, in combination with cortisone, and as a follow-on treatment after 'Irgapyrin.'

None of this series has shown any toxic effects other than (*a*) one case of rather severe gluteal abscess, and (*b*) a few mild macular rashes which have cleared up quickly on discontinuing the drug. In all cases the erythrocyte-sedimentation rate (E.S.R.), white blood-cell count, and platelets are kept under careful observation.

None of these patients has been given a larger dosage than 2 g. per week. (The usual dosage is 1 g. injected intramuscularly twice weekly for four weeks—this course is repeated after an interval of about a month.)

The toxic symptoms reported in your columns have nearly always followed administration of at least 1 g. of butazolidine *daily*, and it would therefore appear that this dosage is too high.

There can be little doubt as to the therapeutic value of butazolidine in rheumatoid arthritis; but the only safe

3. See *Lancet*, July 5, 1952, p. 36.
4. Carter, J. F. B., Milne, E. H., Whittet, T. D. *Ibid*, Oct. 4, 1952, p. 660.
5. Handfield-Jones, R. P. C., Lewis, H. B. M. *Ibid*, 1952, i, 585.

way to administer this drug would seem to be by injection so that the patient can be kept under constant observation and have his white blood-cell count, platelets, and E.S.R. continually reviewed.

The dangers of the tablet preparation are that: (a) the dose of 0·2 g. is rather large for repeated use, (b) digestive disturbances may occur, and (c) the doctor may lose personal control of the supervision of the patient.

I have recently seen two cases of massive œdema of the lower limbs following the use of butazolidine tablets (1·2 g. daily) prescribed by other practitioners.

Coventry and Warwickshire Hospital. JOHN SHULMAN,

SUBLINGUAL HEPARIN

SIR,—Last year Litwins et al.[1] claimed to have increased blood-clotting time by sublingual administration of sodium heparin (125 mg.) in the form of wafers. Clotting-time reached "therapeutic levels" within 30 minutes and were maintained for 4 hours. These workers rightly pointed out the advantages of this mode of administration, especially for the treatment of frost-bite in soldiers on active service.

Because of the importance of this claim we decided to duplicate these experiments in animals.

Rabbits were anæsthetised with sodium pentobarbitone and urethane, and clotting-times were determined on samples of blood taken from the carotid arteries. Intravenous administration of sodium heparin, 1 mg. per kg. body-weight, gave an average clotting-time of 30 minutes, the peak being reached within 10 minutes. With double this dose the average peak was raised to 160 minutes. Intramuscular injection of 10 mg. per kg body-weight raised the clotting-time to about 40 minutes; the plateau was reached within 1 hour and showed no signs of decay after a further 3 hours. Sublingual administration in rabbits anæsthetised with sodium pentobarbitone and urethane had no significant effect on the clotting-time at a level of 10 mg. per kg. body-weight. Doubling the dose had the effect of doubling the normal clotting-time, but in no instance was the "therapeutic level" (20 minutes or more) reached. Likewise oral administration was ineffective.

Since the effect of parenteral administration of heparin in the rabbit resembles that in man, it is not unreasonable to assume that the effect of sublingual administration of heparin in man would be similar to that observed in the rabbit. We therefore concluded that, even should it prove possible to reach the therapeutic levels defined by Litwins and his colleagues with their suggested method of therapy, the dosage required would be massive and the cost prohibitive.

While preparing this work for publication, we were somewhat relieved to see a report by McDevitt et al.,[2] who have also been unable to substantiate Litwins's claim. Consequently we decided that detailed publication of our work was no longer necessary.

Pharmacology Unit,

ANTITHYROID ACTION OF P.A.S.

SIR,—I much appreciate the comments of Dr. Benstock and Dr. Freedman in your issue of Oct. 4.

If, however, it is conceded that all antithyroid drugs act by inhibiting the synthesis of thyroxine in the gland itself and that the enlargement is compensatory and due to the influence of pituitary *thyrotropic* hormone, why should we postulate that the action of P.A.S. should be different and involve a different pituitary hormone—the adrenocorticotrophic one? Unless, of course, one goes a stage further and revives the old hypothesis that there is really only *one* pituitary hormone. The various known fractions could therefore be merely artificial substances created by modern chemical and other techniques!

The exact nature of salicylate action is still sub judice. Until it is finally elucidated, I respectfully suggest that the current concept of antithyroid drug action is equally compatible.

Ilford Isolation Hospital,
Romford, Essex.

I. M. LIBRACH,
Medical Officer in Charge.

Parliament

Flogging for Crimes of Violence

IN the House of Lords on Oct. 22, EARL HOWE called attention to the continuation of crimes of violence towards women and other defenceless persons, and asked whether the existing penalties which the courts had power to inflict were adequate to protect the public. The number of indictable offences known to the police had risen from 283,220 in 1938 to 524,506 in 1951. He suggested that there was more consideration for the gangster than for his victim. The abolition of flogging in 1948 had been described as a great experiment and we were told that it had not yet proceeded far enough to be judged. But, he asked, how many women had to be attacked in circumstances of the utmost brutality before the experiment ended and the public were given the protection to which they were entitled?

Lord GODDARD pointed out that serious crime in this country had increased to such an extent that the criminal work to be done at assizes bade fair to throw the whole legal machine out of gear. He agreed that it was a bad thing to be constantly interfering with the penalties prescribed by law; he believed the time had come when we must consider whether it was not time to re-impose corporal punishment for certain offences, for new and horrible forms of violence were being used. As a judge he disliked having to sentence a young man of 21 or 22 to a long term of imprisonment. Formerly corporal punishment could only be inflicted, with one or two exceptions, for robbery with violence. He suggested that the superior courts should be given power in their discretion to inflict corporal punishment for all forms of felonious violence—not for unlawful wounding, but for felonious wounding, wounding of police while resisting arrest, and attempted murder. He did not want to see the use of the cat reintroduced, and did not believe in the indiscriminate use of the birch. Nor did he believe the reintroduction of corporal punishment would do away with crime, but it might substantially reduce it.

Lord SIMONDS, the Lord Chancellor, said that against the background of a century of penal reform their Lordships were now asked not only to reverse the legislation of 1948 but to extend the penalty of corporal punishment to a degree which surpassed anything that had been permissible for the last 130 years. Was not that in the nature of panic legislation? He was not in a position to say that the Government would introduce such legislation. He asked that the system instituted by the Criminal Justice Act 1948 should be given a fair trial. It provided for preventive detention for persons over thirty for 5 to 14 years, if it was expedient for the protection of the public, and there were now 868 men and 28 women under such detention. Many causes had contributed to the increase in crime; the relaxing of family discipline, the lowering of the general moral standard, and perhaps the failure of religious sanction, were causes. How large a part they played no-one could say, but the Home Secretary thought that the Act should be given a longer trial before they decided to take the step which had been advocated that day.

QUESTION TIME

B.C.G. Vaccination

Dr. BARNETT STROSS asked the Minister of Health what classes of the population were advised to receive protective vaccination by B.C.G. against tuberculosis; and for what reasons this service was not extended to those leaving school.—Mr. IAIN MACLEOD replied: B.C.G. vaccination is at present offered to hospital nurses, medical students, and, at the discretion of chest physicians or other appropriate specialists, to other individuals at special and known risk. Its use in the immunisation of children leaving school is at present the subject of a trial being conducted by the Medical Research Council.

Replying to further questions Mr. Macleod said he feared that the rate of experimentation with B.C.G. vaccine was slow, but in Scandinavia medical opinion was by no means unanimous about its effectiveness, and the Medical Research Council in this country were not yet satisfied that its full effectiveness had been proved.

Mr. P. F. **Remnant**: Is the Minister aware that a very considerable body of opinion in this country, including eminent medical opinion, agrees with this vaccine, and will he see that he is not thwarted by any dilatoriness on the part of the Medical Research Council?—Mr. **Macleod**: It is true that there is a big body of medical opinion in favour of pressing on faster than we are doing with B.C.G., but there is also a large body of medical opinion which holds that we should wait until we know fully whether it will be effective. Dr. **Stross**: Would not the Minister agree that the percentage of reactors among school-leavers is showing an increase, and that the school population therefore shows itself to be more susceptible when leaving school now than formerly? Is that not an important factor?—Mr. **Macleod**: It is a very important factor, and is probably the most valuable field of all for experimentation. The Medical Research Council are, in fact, experimenting in that field now. Mr. **Somerville Hastings**: Is there not a considerable danger in encouraging people to trust to vaccine instead of hygiene and the laws of Nature? No further reply was given.

Assistants' Salaries

Mrs. **Jean Mann** asked the Minister what portion of the Danckwerts award would be passed on to doctors' assistants and trainee apprentices; and how far, in view of this award, he considered it necessary to continue payments to doctors for trainee assistants.—Mr. **Macleod** replied: I cannot say what adjustments in the light of the Danckwerts award will be made in the salaries of assistants, which is a matter for the doctors who employ them. No changes are at present under consideration in the arrangements for paying grants to doctors who supervise the training of assistants.

Mrs. **Mann**: Would the Minister consider making changes in view of the fact that when the Danckwerts recommendations were originally put forward there was no Government grant of £1000 to doctors for what are really locums who help them in their work?—Mr. **Macleod**: I would not agree that this is just a subsidy to locums. I think it has very much more value than that. Both the original scheme and, in consequence, the Danckwerts award were attached to principals, and not to assistants.

Major E. G. R. **Lloyd**: Is the Minister aware that there is some difference of opinion in the medical profession as to how these sums of money should be allocated? Will he consider representations on this subject before the final recommendations are approved by the Government?—Mr. **Macleod**: I have already started implementing the award of the Danckwerts money. It was passed without comment by the House of Commons before the summer recess, but I shall be happy to consider any representations which are made on this important matter.

Hospital Construction

Replying to a question Mr. **Macleod** stated that the capital cost of new hospital construction and extensions, together with the number of additional beds to be provided, in schemes approved by his department since October, 1951, in England and Wales was £5,100,000. The corresponding figure for the previous year was £7,500,000.

Traumatic Surgery

Mr. **Hastings** asked the Minister what arrangements he had made in cases of emergency, such as the railway disaster at Harrow, to draft doctors with specialised experience in traumatic surgery to hospitals in the immediate vicinity, so that the best known treatment might become available to sufferers.—Mr. **Macleod** replied: I am sure the hon. member will agree that the medical aid rendered in this disaster was prompt and efficient. The general surgeons at the hospitals concerned, though not specialists, are experienced in traumatic work. Further help of this nature was offered but not required. The tragedy will be closely studied to see what lessons can be learnt from it. Mr. **Hastings**: Does the Minister realise that traumatic surgery is a specialty of its own? As an instance of that, there are several accident hospitals. Is it not of the greatest importance that people who suffer unexpectedly in this way should in all cases have the very best treatment?—Mr. **Macleod**: I have great sympathy with the hon. member's point of view, but, as I pointed out in my answer, such skilled specialist help was offered and in this case was not required. We will certainly see if there are any lessons that we can learn from this disaster.

Visits to Children in Hospital

Replying to a question, Mr. **Macleod** stated that of the 1300 hospitals admitting children, all except 70 fever hospitals and 75 others allowed regular visiting; 300 allowed daily visits, and the great majority of the remainder allowed visits more than once a week.

Mental Hospitals Accommodation

Replying to a question, Mr. **Macleod** stated that on Jan. 1, 1952, the bed space in use in mental hospitals was overcrowded by 16,000 patients, an average of 13·5%. At the same date the number of unstaffed beds was 1700. The present shortage of staff was about 3500 men and 7700 women. A year ago it was estimated at about 3000 men and 8000 women. The problem was being closely studied by the Mental Health Advisory Committee of the Ministry of Health.

Health-centre Schemes

Replying to a question, Mr. **Macleod** said that since October, 1951, one health-centre scheme had been approved, and this centre and two others approved before that date had been completed.

New Treatment for Cataract?

Mr. J. A. **Sparks** asked the Minister what steps he was taking to make available to persons suffering from cataract blindness the new cure discovered by the New York Cataract Institute in the use, by injection, of protein substances from the lenses of fishes' eyes.—Mr. **Macleod** replied: I am advised that the claims made for this treatment are so far unsubstantiated.

Toxic Effects of Detergents

Dr. **Stross** asked the Minister what evidence was available of the toxic effects following the use of detergents in cleansing glass and crockery; and what figures he had as to the incidence of dermatitis following their use.—Mr. **Macleod** replied: I am not aware of any. Dr. **Stross**: Has the Minister not been made aware that detergents tend to cause dermatitis, chapped hands, and so on? Is he not aware that it is agreed that if glasses and crockery are not adequately washed after being dipped into detergents a cumulative dose is gradually taken into the human body and that that is not good for it?—Mr. **Macleod**: I do not dispute that, but that is not the question that I have been asked. I have inquired from the Minister of Labour and the Minister of National Insurance and they have no such evidence as was referred to in the question.

Foot-and-mouth Disease

In the House of Lords on Oct. 21, replying to the **Earl of Listowel**, Lord **Carrington**, joint parliamentary secretary to the Ministry of Agriculture, said that in recent weeks the amount of foot-and-mouth disease in this country had been so much reduced that after midnight of that day, if all went well, there would be only one infected area left. In September there were 13 outbreaks, compared with 19 in August and 51 in July. So far in October, there had been only 3 outbreaks, all in Hampshire, and no outbreaks had been reported since Oct. 6. Since Nov. 1, 1951, there had been 582 outbreaks in all, and the compensation payable to farmers amounted to about £2,738,000. On the whole, the position in Western Europe was much less ominous than a year ago, and there was at present no reason to expect this autumn a major invasion of the disease from the Continent such as was experienced last autumn and earlier this year.

He added that at an international conference convened by the Food and Agriculture Organisation of the United Nations at which 13 European countries, including the United Kingdom, were represented, it was agreed to recommend that a European Commission for foot-and-mouth disease should be appointed to stimulate and coördinate national and international control of this disease. This recommendation still had to be studied in detail by the governments concerned, but a body of this kind could, he thought, do much to prevent a repetition of last year's disastrous epidemic in Europe and minimise the risk of disease spreading to this country.

Vitamins in Food

Replying to Dr. STROSS, Mr. MACLEOD, Minister of Health, said that the report of the Standing Committee on Medical and Nutritional Problems on the possibility of excessive consumption of vitamins due to food fortified by these substances had been referred to the departments concerned for their consideration. It appeared from the report that in present circumstances there was no danger of excessive consumption of vitamins due to food fortified with these substances.

Children and Tuberculosis

In answer to a question Mr. MACLEOD stated that a survey conducted by a committee of the Medical Research Council in 1949–50 in 22 selected areas on a sample basis showed that 56·1%, over all, of children aged fourteen and 48·5% of those aged fifteen to sixteen were tuberculin-negative, and that there was some evidence that these percentages were increasing.

Public Health

Shortage of Health Visitors

THE public-health section of the Royal College of Nursing thinks that the present complement of health visitors is quite inadequate to carry out the wider duties implicit in the National Health Service Act. Where the annual number of new recruits should be 900 it is now little more than 500, and some 25% of places in approved centres are not taken up. In addition, and partly as a result of this shortage the health visitor's proper sphere is being invaded (it is felt) by a host of other workers with a shorter training and higher remuneration. Though this discrepancy in pay is certainly a contributory factor, the main deterrent to newcomers to the service is believed to be the sense of frustration and disillusionment to be found among the health visitors themselves.

The council of the college is asking the Minister of Health to set up a committee to review the training, employment, and prospects of the health visitor, and to clarify not only her position under the local health authority but that of others working in kindred fields and also fields which the health visitor feels to be her own. The Minister will shortly have the results of the Nuffield analysis of the work on which the health visitor is at present engaged; and the moment is appropriate in view of his recent pronouncements on the need to strengthen the clinic, domiciliary, and family-doctor services as a means of relieving pressure on costly hospital beds. Much has been done to improve the position of hospital nurses, but too little, it is felt, to capture the imagination of possible recruits to public-health nursing.

Examination of Coalminers

Draft regulations issued by the Minister of Fuel and Power (Coal Mines [Medical Examinations] General Regulations, 1952) lay down that all those under 21 entering employment in or about coalmines shall be medically examined, with certain exceptions. The regulations prohibit the employment of anyone in work for which he is found on examination to be unfit. The draft regulations do not specify the form of examination, nor do they mention repeated examinations throughout the period of employment.

Statistics for England and Wales

In England and Wales during the June quarter[1] the birth-rate was 16·0 per 1000 population. This was the lowest rate since 1942; the average for the five years 1946–50 was 18·8. The stillbirth-rate—22·4 per 1000 live and still births—was the lowest ever recorded for a June quarter in this country. The death-rate was 10·6 per 1000 population, compared with 11·1 in the two previous June quarters. The infant-mortality rate of 25·1 per 1000 related live births represented a drop of 3·6 from the rate in the June quarter of 1951, and was the lowest yet recorded for the quarter in this country. The excess of births over deaths was 58,683, compared with 72,066, 60,552, and 59,660 in the June quarters of 1949, 1950, and 1951.

The Registrar-General has also reported provisional figures for the third quarter,[2] which, together with the corresponding figures for earlier years, are as follows:

Third quarter of		*Live births per 1000 pop.*		*Stillbirths per 1000 total live and still births*		*Deaths per 1000 pop.*		*Deaths of infants under 1 yr. per 1000 related live births*
1952	..	15·3	..	21·5	..	9·0	..	23·0
1951	..	15·2	..	21·8	..	9·1	..	23·4
1950	..	15·4	..	22·5	..	9·3	..	23·9
1938	..	15·2	..	37·0	..	9·9	..	42·5

Thus the fall in the birth-rate since 1947 has been arrested. The death-rate was the lowest since the September quarter of 1947. Both the stillbirth-rate and the infant-mortality rate were the lowest ever recorded for any quarter in this country.

Infective Hepatitis in the U.S.A.

In the U.S.A. the total number of cases of infective hepatitis in the thirty-nine weeks of this year up to Oct. 4 is provisionally estimated at 11,868.[3] The incidence was highest in the winter and spring months, and in the States of Alabama, Georgia, Kentucky, and West Virginia. Epidemics have been reported most often from States with large rural populations, and commonly in schools. In two outbreaks water was regarded as the vehicle of infection; but in most instances epidemiological evidence has pointed to person-to-person spread. In one instance handling of soiled linen used by infectious patients in hospital seems to have been the means of transmitting infection.

Obituary

WILFRED WATKINS-PITCHFORD

M.D. Lond., LL.D. Witwatersrand, F.R.C.S., D.P.H.

Dr. Watkins-Pitchford, the first director of the South African Institute for Medical Research and a former vice-president of the British Medical Association, died on Sept. 29 at the age of 84.

He was educated at St. Olave's Grammar School in Southwark, where his father was vicar of St. Jude's, and in 1891 he qualified from St. Thomas's Hospital. After holding resident appointments there he took his F.R.C.S. in 1897, but he was deflected from a possible career in surgery by the offer of an appointment in Natal, where his brother Lieut.-Colonel Herbert Watkins-Pitchford was chief veterinary officer. He spent the next few years advising the government of Natal on the plans for the establishment of their new bacteriological laboratory. In 1898 he was appointed as a special plague officer to the government of Bombay. After serving as a civil surgeon during the Boer War he returned to England in 1901, to take the D.P.H. at Oxford. While he was at home the smallpox epidemic of 1902 occurred, and in view of his experience in the Far East he was appointed consultant to the London County Council. The same year he took his M.D. Lond. in State medicine.

Shortly afterwards he returned to Natal as assistant bacteriologist to the government, and in 1907 he became pathologist and analyst. In 1911 he moved to Johannesburg, where he became government pathologist and bacteriologist to the Transvaal. He also held the posts of municipal public analyst and of honorary pathologist to the Johannesburg General Hospital.

When the South African Institute for Medical Research was set up in 1912 he was appointed its director. In 1914 he published a monograph on *Industrial Diseases of South Africa*, and when the Miners' Phthisis Board was formed in 1916 he became chairman of the medical bureau. His contributions on silicosis, published in the annual reports of the board, described what was at that time the most comprehensive and intensive inquiry ever made into the occurrence of any disease.

---

[1] Registrar-General's Quarterly Return for England and Wales: Quarter ended June 30, 1952. H.M. Stationery Office. Pp. 27. 2s. 6d.

[2] Registrar-General's Weekly return for England and Wales: Week ended Oct. 18, 1952. H.M. Stationery Office. Pp. 20. 1s.

[3] Morbidity and Mortality: Weekly Report, Federal Security Agency, Public Health Service: Oct. 10, 1952.

During the 1914–18 war Watkins-Pitchford added to his heavy burden of work the task of editing the *South African Medical Journal*. He saw bacteriology as a discipline of the science of preventive medicine, and his appointments outside his specialty included membership of the Union of South Africa's Council of Public Health and Leprosy Advisory Committee. He was also honorary professor of pathology and bacteriology in the University of Witwatersrand, and on his retirement in 1926 he received from it the honorary degree of LL.D. His work for the British Medical Association during his years in South Africa was recognised by his appointment as vice-president in 1923.

On his return to England he settled at Bridgnorth in Shropshire, where his friends were able to watch with pleasure the improvement in his health and the increasingly active part he was able to take in local affairs.

A. J. O. writes: "Two outstanding services were rendered by Wilfred Watkins-Pitchford: he was the first director of the South African Institute for Medical Research, and he was the first chairman of the Miners' Phthisis Medical Bureau. When he was appointed director of the S.A.I.M.R. there was a fine building designed by the late Sir Herbert Baker, a small amount of elementary equipment, and no staff. Soon there was a staff of half a dozen. From this grew the present great institute. When he retired Watkins-Pitchford left the institute in full swing. The Medical Bureau was established in 1916, the first institution of its kind in the world. It was, and still is, the sole authority for the medical examinations of miners, pre-employment, periodical, and for certification of the presence and degree of silicosis. With the late Louis Irvine, Watkins-Pitchford laid down the plan of work for the bureau which for many years continued to function admirably. A modest man of much personal charm and kindness, he had many friends in South Africa, few of whom, alas, are still alive."

Dr. Watkins-Pitchford married in 1905 Olive Mary Nicholl. They had a daughter, and a son who is a doctor.

Sir TRENT CHAMPION de CRESPIGNY, D.S.O., F.R.C.P., a former president of the Royal Australasian College of Physicians, died at his home at Adelaide, on Oct. 27, at the age of 70. For many years he was dean of the faculty of medicine of Adelaide University, and he was also chairman of the council of the Institute of Medical and Veterinary Science of Adelaide.

Births, Marriages, and Deaths

BIRTHS

BROMFIELD.—On Oct. 22, at the Canadian Red Cross Memorial Hospital, Taplow, Bucks, to Anne (née Powell), wife of Dr. Frank Bromfield—a son.

FISHER.—On Oct. 12, to Sylvia, wife of Dr. J. A. Fisher, of Clonelly, Magherafelt, co. Derry—a daughter.

LITTLEWOOD.—On Oct. 15, to Elizabeth, wife of Dr. Arthur William Littlewood, of Gillits, Natal, South Africa—a daughter.

MILTON.—On Oct. 19, at Southchurch, Haslemere, to Joan, wife of Dr. R. Milton—a son.

WALKER.—On Oct. 19, to Elizabeth (née Barton), wife of Dr. Richard Walker, of Whitchurch, Hants—a son.

MARRIAGES

MACDONALD—DAVIES.—On Oct. 18, at Bolney, Sussex, Duncan [illegible] B., to Rosemary Ann Davies.

[illegible]—On Oct. 18, at Chiswick, Geoffrey [illegible] B., to Teresa Elizabeth Tomlinson.

DEATHS

BAYON.—On Oct. 20, at Little [illegible] Henry Peter Bayon, M.D. Genoa and Ca[illegible]

BURT-WHITE.—On Oct. 20, at [illegible] Burt-White, M.D. Lond., F.R.C.S., M.R.C.O.G.

EASTERBROOK.—On Oct. 25, at Gowanbrae, Eskbank, Dalkeith, Midlothian, Alexander Maitland Easterbrook, M.B. Edin., aged 83.

REDMOND-HENDERSON.—On Oct. 21, Sidney Redmond-Henderson, husband of Dr. Winifred Redmond-Henderson.

SILLAR.—On Oct. 23, William Cameron Sillar, M.D., B.SC. Edin., of the Gables, Wheatley, Oxon, aged 88.

SMEED.—On Oct. 25, Edward Smeed, M.R.C.S.

TALENT.—On Oct. 17, at Newlands, Grange over Sands, John William Talent, M.D. Edin.

THOMAS.—On Oct. 19, Frank Leslie Thomas, M.B. Lond., of the Square, Barnstaple.

WALKER.—On Oct. 21, at Springbank, New North Road, Huddersfield, Albert Edward Walker, M.B.E., M.D. Edin., aged 89.

Notes and News

ALCHEMY

"Let chemists toil like asses," Gay's highwaymen sing, "Our fire their fire surpasses, and turns all our lead to gold." We, who know at last that metals really can be transmuted, declining from uranium to lead, are yet apt to wonder at the passion with which our learned ancestors, with very little to go on, believed in the Philosophers' Stone. And indeed the mystery which hangs about alchemy is real and strange, as Mr. F. Sherwood Taylor, PH.D., makes clear in his little book, *The Alchemists*,[1] For one thing, only the meaner sort among them were seeking gold. The true alchemists were feeling their way blindly towards perfection—of the base metal, certainly, but also and chiefly of their own natures. Moreover, they believed it to be a lost perfection, which men had once known how to recover. Where we are looking anxiously forward they were looking nostalgically back. No-one could hope to be an alchemist until he had been instructed by a master of the art; for though there were texts available—some ancient and of great authority—which gave recipes for making the red and the white stones, with their marvellous properties, they were written in a style so deliberately obscure that the uninitiated could not understand them. Even now it is impossible to decipher more than a fraction of their meaning. Yet after instruction, it seems, the neophyte could follow them without difficulty. That is not to say he was forthwith in reach of making the Philosophers' Stone. The method was so lengthy and the risks to apparatus so formidable that he was likely to spend years in failing and starting afresh—years which he expected to use in preparing himself spiritually for the responsibilities of success. It is not possible for us to suppose that anyone ever succeeded; yet there are circumstantial accounts by those who say either that they did, or that they were given a tiny particle of the stone by an alchemist and worked the marvel of transmutation with it. Of course they had no exact means for assaying gold—which accounts for the readiness with which they accepted recipes for "doubling" gold (actually by debasing it with other metals in alloy).

Alchemy is often said to be the forerunner of chemistry; and certainly the alchemists had opportunities to observe a multiplicity of chemical reactions. Their attention, however, was elsewhere, and they have left us no record of these changes. What they did bequeath us was some first-class laboratory equipment—stills, flasks, furnaces, lamps, water-baths, ash baths, reverberatory furnaces, crucibles, dishes, beakers, pestles and mortars, strainers, filters, stirring-rods, and much other convenient apparatus still in use today. They had no conception of the freemasonry among scientists which we are now losing, and which made every new discovery the common property of the scientific world. But then, their reason for secrecy was a better one than ours: they feared that if knowledge of the art was put within reach of unscrupulous men, it might not be used for the glory of God and the benefit of mankind.

EMERGENCY BED SERVICE

THIS year, during the winter months, we shall again be publishing in our news columns figures showing the number of applications for beds for acute cases dealt with each week by the London Emergency Bed Service. The applications include those from general practitioners and from hospitals wishing to transfer patients from their casualty outpatient departments. The gap between the number of applications and the number of admissions is not composed entirely of cases that fail to be admitted: some cases are withdrawn by the doctor or the hospital while the service is still looking for a bed, and some patients refuse to go to hospital when a bed has been found, or die before admission.

HOSPITALS YEAR BOOK

ANOTHER October has brought a new edition of the Institute of Hospital Administrators' yearbook (obtainable from the Institute, 35, Portland Place, London, W.1: 1952. Pp. 1402. 45*s*.), and, though there may be more exciting reading for fireside evenings, anyone who is interested in our health services will find in its pages many useful facts set out in easily accessible form. The addresses and names of the chief officers of the bodies which administer the health service are given, from the Ministry in Whitehall to the executive council in Zetland and the hospital management committee at Morgannwg, and the list of less formal voluntary bodies who lend a valuable helping hand ranges from ASLIB to the W.V.S. In the section on reference information for the hospital administrator the value of the list of statutory instruments, memoranda, and circulars is increased by a useful index. As Mr. J. F. Milne, the editor, in his opening survey points out, it would be unfortunate if the present natural and perhaps inevitable concentration of interest on finance were allowed "to obscure the achievements which the national hospital service, in the comparatively short space of four years, has already to its credit." In offering so much useful information about our health services the yearbook reminds us that there is now a good deal to be informative about.

---

HEBERDEN SOCIETY

ON Oct. 25, Lord Horder delivered the Heberden oration taking as his subject Rheumatism—a National Problem. Sir Henry Cohen, the president of the Society, presented the Heberden medal to Lord Horder for his original observations and research in rheumatism.

DIRECTORY OF RESEARCH

IN 1946 a list of the research being carried out in British universities was prepared for an Empire scientific conference. The list was taken over by the British Council for its own use, but there have been so many requests for copies that the Department of Scientific and Industrial Research has now arranged to publish it each year. The British Council will continue to collect the material. *Scientific Research in British Universities 1951–2*, which is now available from the Stationery Office (8*s*., by post 8*s*. 6*d*.) gives details of research work in universities and colleges in the United Kingdom. It covers all fields of science and technology, including medicine. The names of the staff working on each problem and enough description to show the scope of the research are given in the main list, which is arranged according to university. There is also an index of names at the end so that any worker may be easily traced to his academic base.

FRIENDS' WORK

IN *Quaker Relief*[1] Mr. Roger Wilson, general secretary of the Friends Relief Service, modestly but effectively describes the many kinds of work which some 1200 men and women chose as an acceptable way of rendering their National Service other than in the Armed Forces. Not all of them were Quakers, but all had accepted the full implications of the pacifist rôle, and they were allowed to do this service as conscientious objectors. He explains a good deal about the background of committees, for nothing goes on its sober Quaker path without the appropriate committee backing. But delightful touches tell us of how, here and there, the headstrong team, or individual, would act first, and see about the permission later; and it seems as if the general secretary was able to suit his blind or watchful eye to every occasion.

In this country the work was usually some form of social service—among hop-pickers, among evacuees, in air-raid shelters, or for new settlers on housing estates. Abroad, teams, largely of American Friends, helped refugees after the Spanish Civil War and from Alsace in 1940. The Friends Ambulance relief team worked with the 21st Army Group, alongside the British Red Cross. In Greece a domestic school for girls remains a very successful piece of work. Episodes in Germany, Austria, Holland, Poland, and (outside Europe) Palestine and East Africa round off a tale of absorbing interest.

The members of the relief service, by the ability to live and work together, to forego comfortable living, and to share physical discomfort with their victims, gave their work a particular quality of sincerity and effectiveness. Reading this book one is reminded of Bunyan's hymn: "He who would valiant be, 'gainst all disaster." And what a telling quality valiance has in a disaster.

FILM ON HEMIBALLISMUS

A COLOUR film on *Hemiballismus in a Woman aged 71 Years* records the case of an old lady with severe choreiform movements of one side of the body. The movements are well shown, and there is a diagram depicting the site of the lesion in the subthalamic nucleus. Although some of the shots are rather long and some are reduplicated, this is nevertheless an excellent teaching film. The film (16 mm., silent) was made in 1950 for the National Hospital, Queen Square, by the department of medical illustration, Guy's Hospital, London.

A NEW JOURNAL OF PROJECTIVE TECHNIQUES

THE origins of the Rorschach test are to be found in several countries: the doctor-poet Justinus Kerner published his book on *Kleksographien* in Germany a hundred years ago, Alfred Binet provided a French contribution in 1895; and since Rorschach's brilliant work, investigators in America, England, and many other countries have illuminated the subject. Articles have appeared in widespread journals, including the *Rorschach Research Exchange* (now known as the *Journal of Projective Techniques*). The appearance of *Rorschachiana*, an international review of Rorschach and other projective techniques (Berne and Stuttgart: Huber), is to be welcomed, for it was in Switzerland that the notable studies of Hermann Rorschach were carried out. This well-produced quarterly has a strong Swiss backing but a widely representative editorial board, and should provide a forum not only for Rorschach studies but for reports on other projective methods developed since his untimely death. The languages to be used will be English, French, German, and Latin (and possibly also Spanish). In the opening number there are instructive contributions by Professor Bleuler, Dr. Loosli-Usteri, and Dr. Kadinsky, in the three main languages of today; except on the front page and the last, there is nothing to suggest that readers of the journal need to brace themselves forthwith for a tussle with the Latin periods of some expert reared in the grand traditions; at all events, since Mr. K. W. Bash, the editor, threatens to reject any paper that is not "stilistically correct," there is no danger that the writers of a debased Silver Age style—"Ulpian at the best"—will be allowed to affront the international Rorschach public.

THE EVOLUTION OF PLANTS

CERTAIN non-living chemical substances can interact to produce other substances very difficult to distinguish from living matter. Protein is supposed to have arisen in this way. If a particle of protein interacted with other substances to form more protein like itself it would be a virus. If this was indeed the way in which living organisms first came into being, it means that the earliest of them were not autotrophic (making their organic food from inorganic substances) but heterotrophic (obtaining their organic food from organic material) and that autotrophic organisms evolved from heterotrophic. Possibly some heterotrophic organisms gradually acquired the power of setting up chain reactions, and such an organism would gain if it could prevent dispersal of the products of earlier reactions in the chain likely to be required for the later reactions. Thus any organism which acquired a protective envelope would have a better chance of survival than most, and this would be the beginning of the cell and its semipermeable membrane.

The next step would be towards sexual reproduction, which enormously increases the rate of evolution by natural selection. Every organism that reproduces sexually has its life-cycle divided into two parts—haploid, with single chromosomes; and diploid, with double chromosomes. But these parts are not equal. In almost all animals the organism is mainly diploid, with but a brief haploid phase without mitosis. In many of the simpler plants the opposite is true, but in most plants both haploid and diploid cells undergo mitosis (alternation of generations). These facts suggest that sexual reproduction evolved before animals and plants diverged from one another—in fact, in a unicellular organism. The simplest form of sexual reproduction would be the fusion of two unicellular haploid organisms to form a diploid one, followed by meiosis producing haploids, and *da capo*.

A multiplicity of algal types shows that before vegetable life invaded the dry land it had undergone a long and complicated evolution. Whitehouse[1] suggests that the land plants have evolved from a fresh-water plant with a protected egg-cell enabling it to withstand a period of drought. The three classes of land plants—(1) mosses and liverworts, (2) ferns, club-mosses, and horsetails, and (3) seed-plants—have in common five important features: a protected egg-cell, alternation of generations, a cuticle, stomata, and air-spaces. Algæ do not share these features, which suggests that land plants are not descended from algæ but from a common ancestor shared with algæ. Of the three classes of successful land plants the mosses and liverworts "still show traces of their aquatic ancestry in their mode of fertilisation, and in this respect may be regarded as incompletely adapted for life on ıd." Whitehouse calls them "a blind alley of evolution." them the haploid phase predominates over the diploid. The final step in botanical evolution was the development of ɜd-plants. The elaboration of the haploid phase in mosses d liverworts rendered these plants incapable of eliminating ə need for external water. The abbreviation of the haploid ase enabled the ferns to evolve into seed-plants. This was ne by developing two kinds of sporangia, one containing ge female spores with a plentiful food-supply, and the her containing small male spores. Sometimes the female ores were retained on the diploid plant, their food being pplied direct from the parent; then, for fertilisation to take ace, the male spores must germinate near the female orangia and not on the ground. Such features can be cognised in fossils of the Carboniferous age (c. 300 million ars ago). In the succeeding Permian age (c. 250 million ars ago) the reproductive method had evolved still further. ıe female sporangia were protected by an integument, rming *ovules* which, after fertilisation by male spermatozoids, gan to develop into new plants but stopped after a time and came *seeds* for dispersal. Moreover fertilisation no longer pended on the presence of extraneous water: the necessary quid was derived from the male spores and from the breakown of the tissues of the apex of each female sporangium. or, in remembrance of their aquatic origin, the spermatozoids plants still have to swim for it, like human spermatozoa.

niversity of Cambridge

Dr. A. D. Gardner, regius professor of medicine in the niversity of Oxford, has been appointed Rede lecturer for 953.

Prof. H. R. Dean has been re-elected as representative of ıe university on the General Medical Council for a further ve years.

niversity of Leeds

The title of emeritus professor has been conferred on rof. J. W. McLeod, F.R.S., who lately retired from the rotherton chair of bacteriology.

Mr. P. J. Moir, who held the chair of surgery from 1940 to 946, and who has been elected dean of the faculty of medicine, as been appointed professor of surgery from Oct. 1. For the ime being Prof. Digby Chamberlain will continue to act as ead of the department of surgery.

oyal College of Physicians of London

Prof. Alan Moncrieff will deliver the Charles West lecture n Tuesday, Nov. 11, at 5 P.M. at the college, Pall Mall East, S.W.1. His subject will be Infection in the Newborn Baby.

Royal College of Surgeons of Edinburgh

At a meeting held on Oct. 22 the following officers were elected:

President, Prof. Walter Mercer; vice-president, Mr. W. Quarry Wood; secretary and treasurer, Mr. J. J. Mason Brown; members of the president's council, Prof. R. C. Alexander, Mr. K. Paterson Brown, Mr. John Bruce, Mr. Arthur Hamilton, Mr. James Jeffrey, Mr. Archibald Brown Kerr, Sir James Learmonth, Mr. Robert Mailer, Dr. David Middleton, Mr. T. McWalter Millar, Dr. Douglas Miller, and Mr. R. Leslie Stewart; representative on the General Medical Council, Sir Henry Wade; conservator of museum, Mr. J. N. Jackson Hartley; convener of museum committee, Mr. John Bruce; librarian, Dr. Douglas Guthrie.

The following were admitted to the fellowship:

Amirali Abdulkarim Alidina, Gurbux Singh Babbar, K. L. Barnes, A. K. Brown, Jitendrarao Vajendrarao Desai, Sami Salim Khoury, Manijah Khudabux, Herbert Kramer, R. C. W. Lowe, J. D. Malloch, Naizhy Noble, R. D. Oatway, F. F. Sandor, L. A. Scrivin, Gurmukh Singh Sekhon, Shailendra Kumar Sinha, J. R. Smith, D. M. Stevens, N. P. Stracey, S. E. Wijetilaka.

Royal Australasian College of Physicians

The following have been admitted to the membership:

John Beveridge, R. S. Colton, M. Faunce, Alison K. Garven, Donald F. King, G. S. Nagy, A. Jean Palmer, I. S. Wallman.

Royal Institute of Public Health and Hygiene

On Dec. 9, 10, and 11, at 4.30 P.M., at the institute, 28, Portland Place, London, W.1, Lord Horder will deliver the Harben lectures. He is to speak on Fifty Years of Medicine.

North of England Otolaryngological Society

The following officers have been appointed for 1953: president, Mr. R. R. Simpson; vice-president, Mr. J. M. Wishart; immediate past president, Mr. G. S. Seed; secretary, Mrs. F. Cavanagh; members of council, Mr. R. Thomas, Mr. J. I. Munro Black, Mr. R. S. Venters, and Mr. J. D. Gray.

Mothercraft Exhibition and Conference

This exhibition and conference which opened at the Central Hall, Westminster, S.W.1, on Oct. 30 will continue until Nov. 12.

Royal Society of Arts

Mr. P. W. Brian, SC.D., of Imperial Chemical Industries, will deliver three Cantor lectures on Mondays, Nov. 17, 24, and Dec. 1, at 6 P.M., at the house of the society, John Adam Street, Adelphi, London, W.C.2. He will speak on Microbiology.

First-aid in Mines

A portable first-aid room, which can be moved forward as the coal face advances, is on trial at Markham no. 1 colliery, near Chesterfield. It is 12 ft. long, 6 ft. high, and 6 ft. wide, and contains a cabinet on wheels, for quick transmission, trestles, stretcher, eye-lamp, two chairs, dressing-bin, freshwater containers, and flasks of tea.

Research into Ageing

The research committee of the International Association of Gerontology consists of an American and a European division. The European division held its meeting at Liège on Sept. 25–27, under the presidency of Prof. L. Brull. The officers of this division are Prof. A. P. Thomson (chairman), Professor Brull, and Dr. V. Korenchevsky (hon. secretary), and those attending from this country included Prof. J. B. Duguid, Prof. Alexander Haddow, Dr. W. H. Lloyd, and Prof. Alexander Kennedy. The committee will hold sessions at the third International Gerontological Congress, which is to be held at Oxford in July, 1954.

Practice Arrangements

At a meeting of London Executive Council on Oct. 23, the general benefits committee reported the case of a practitioner with a list of 3936 health-service patients who is also employed by an industrial company. According to the report, a check had shown that the majority of prescriptions for this practitioner's patients were issued by his assistant. The committee had formed the opinion that the doctor should do at least half of the work of the practice and should attend morning and evening surgeries. The doctor had been given a month to review the position, and had been informed that, if his proposals were unsatisfactory, it might be necessary to ask the medical service committee to investigate the conduct of his practice.

Society of Medical Officers of Health

At the dinner of this society in London on Oct. 23, Mr. Iain Macleod, the Minister of Health, expressed pleasure at being in a gathering "that is almost entirely Scottish." He urged members not to mourn too much the passing of hospitals from their control. He was less happy about the relation of local authorities to the National Health Service; but a solution of this problem might have to await a more rational arrangement of local-authority boundaries—a task that no Government with a small majority would care to undertake. Mr. Macleod had heard that the society was considering a change in its name; and he suggested that "preventive medicine" might be incorporated in the new title. Mr. Macleod then proposed The Society; and in his reply Dr. Andrew Topping, the president, suggested that the achievement of local authorities between the passing of the Local Government Act of 1929 and the start of the National Health Service had not been fully appreciated. He still rued the passing from the M.O.H.'s control of the tuberculosis and infectious-disease hospitals, with their social implications. Dr. Topping also held that general practitioners should have a better status; they could, he thought, work more commonly in hospitals. Dr. C. F. White spoke in kindly terms of The Guests; and Mr. George North, LL.D., and Prof. G. S. Wilson responded.

EMERGENCY BED SERVICE.—In the week ended last Monday, applications for general acute cases numbered 1060. The proportion admitted was 92·4%.

The International Congress of Medicine and Military Pharmacy which was to have been held in Montevideo in March, 1953, will not now take place.

Prof. F. Grundy has been appointed a member of the committee set up by the Minister of Food to inquire into the law and the practice of the slaughter of horses.

Surgeons and technicians from seven countries are now attending a two-week training course at Queen Mary's Hospital, Roehampton, on the manufacture and fitting of artificial limbs and the rehabilitation of amputees. The course is sponsored by the World Veterans Federation and the International Society for the Welfare of Cripples, and the Ministry of Pensions has provided facilities and personnel.

Diary of the Week

NOV. 2 TO 8

Monday, 3rd

SOCIETY OF APOTHECARIES OF LONDON, Black Friars Lane, Queen Victoria Street, E.C.4
3.30 P.M. Mr. T. Holmes Sellors: Surgery of Diseases of the Chest.
5 P.M. Sir Geoffrey Todd: Medical Aspects of Diseases of the Chest.

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Prof. N. J. Scorgie, B.SC.: Animal Epidemiology.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5 P.M. Prof. Arnold Sorsby: Streptomycin and other Newer Antibiotics.

Tuesday, 4th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene, Keppel Street, W.C.1.) Sir Bryan Matthews, F.R.S.: Life at High Altitudes.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8.30 P.M. *Section of Orthopædics.* Mr. J. G. Bonnin, Mr. E. Mervyn Evans, Mr. J. A. McLaughlan, Mr. R. H. Metcalfe: Fractures in the Aged.

SOCIETY OF APOTHECARIES OF LONDON
3.30 P.M. Sir William Gilliatt: Changes in Obstetrics and Gynæcological Practice in Last Fifty Years.
5 P.M. Dr. Kenneth Harris: Pitfalls in Diagnosis of Coronary Thrombosis.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. C. O. Carter: Genetics.

WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck Street, W.1
5.30 P.M. Dr. C. Worster-Drought: Neurological demonstration.

Wednesday, 5th

ROYAL SOCIETY OF MEDICINE
8 P.M. *Section of Surgery.* Mr. R. C. Brock, Prof. C. G. Rob, Mr. Frank Forty: Reconstructive Arterial Surgery.

SOCIETY OF APOTHECARIES OF LONDON
3.30 P.M. Dr. Robert Forbes: Medicolegal Hazards in General Practice.
5 P.M. Dr. R. Hale-White: Present and Future Trends in General Practice.

ROYAL EYE HOSPITAL
5.30 P.M. Mr. L. H. Savin: Differential Diagnosis of Headache.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. C. H. Andrewes, F.R.S.: Work of World Influenza Centre.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. J. O. Oliver: Epitheliomata.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Mr. H. G. Hanley: Urological Problems during Pregnancy.

SOCIETY OF APOTHECARIES OF LONDON
3.30 P.M. Sir Horace Evans: Medical Aspects of Hypertensive Disease.
5 P.M. Mr. A. Dickson Wright: Surgical Management of Hypertension.

MIDLAND MEDICAL SOCIETY
8.15 P.M. (*Birmingham Medical Institute.*) Prof. Melville Arnott, Mr. A. L. D'Abreu: Management of Mitral Stenosis.

MANCHESTER MEDICAL SOCIETY
4.30 P.M. (University of Manchester.) *Section of Medicine.* Dr. W. G. Oakley: Diabetes.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8.30 P.M. (Royal College of Surgeons, 18, Nicolson Street.) Dr. J. K. Slater, Dr. Montague Hadley: Coal Gas Poisoning.

Thursday, 6th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. R. R. Bomford: Changing Concepts of Health and Disease, with particular reference to "Psycho-somatic Medicine." (Bradshaw lecture.)

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
4.30 P.M. Dr. C. F. Hadfield: Random Reminiscences of Fifty Years. (Frederic Hewitt lecture.)

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. Group-Captain W. K. Stewart: Physiological Effects of Gravity.

UNIVERSITY OF LONDON
5 P.M. (1, Wimpole Street, W.1.) Prof. Arthur W. Proetz (St. Louis): Clinical Aspects of Respiratory Air Currents. (Semon lecture.)

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION
2.15 P.M. (1, Wimpole Street, London, W.1.) Dr. W. Rees Thomas: The Unwilling Patient. (Maudsley lecture.)

ROYAL EYE HOSPITAL
5.30 P.M. Miss J. M. Dollar: Squint.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. Haber: Specific and Foreign Body Granulomas.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Co S.W.1
5 P.M. Dr. Denis Williams: Neurological lecture-demonstra

LIVERPOOL MEDICAL INSTITUTION, 114, Mount Pleasant, Liverp
8 P.M. Mr. John Hamilton: Avoidable Stillbirths and Neo Deaths.

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Mr. J. R. Cameron: Melanoma.

UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Prof. J. Duguid: Cholesterol and Atherosclerosis.

Friday, 7th

ROYAL SOCIETY OF MEDICINE
10.30 A.M. *Section of Otology.* Air Vice-Marshal E. D. D. Dicks Effects of Intense Sound and Ultra-sound on the Ea (Presidential address.)
2.30 P.M. *Section of Laryngology.* Mr. J. P. Stewart: Use Cortisone in Allergic Rhinitis. (Presidential address.)
5.30 P.M. *Section of Anæsthetics.* Dr. M. D. Nosworthy: Aids Anæsthesia. (Presidential address.)

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. J. Wallace: Congenital and Developmen Abnormalities.

ROYAL EYE HOSPITAL
5 P.M. Dr. J. Blewett: Diagnostic Value of X rays in Ophthalm Work.

Saturday, 8th

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W.C.1
11.30 A.M. Dr. Proetz: Olfaction.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
NOON. (Hammersmith Hospital, Ducane Road, W.12.) Prof. W. I. C. Morris: Uterine Rupture.

Appointments.

BOLAND, C. R., M.A., M.D., M.SC. Dubl., F.R.C.S.I.: surgeon, S Kevin's Hospital, Dublin.
BOVERI, R. M., M.D., L.R.C.P.E.: asst. chest physician, Herefordsh group of hospitals and Herefordshire county council.
KERTESZ, ANDREW, M.B. Lond., D.C.P., D.T.M. & H.: asst. pathologist, General Hospital, Nottingham.
MACCARTHY, H. M., F.R.C.S.I., M.R.C.P.I., F.A.C.S.: surgeon, S Kevin's Hospital, Dublin.
NORTH, J. F., M.A., M.B. Camb., F.R.C.S.: part-time consultant plastic surgeon, Dudley and Stourbridge group of hospitals.
TILLEY, ROBERT, M.R.C.S., D.P.H.: appointed factory doctor, Ho district, Kent.
WILLIAMS, A. H., M.R.C.S.: appointed factory doctor, Bargo district, Glamorganshire.

East Anglian Regional Hospital Board:

ASCROFT, N. O., M.B. Lpool: medical registrar, Foxhall Hospital
KEYES, MARY, M.B. N.U.I.: medical registrar, Papworth Hospital
PETTIGREW, R. W., M.B. Edin.: senior registrar in chest medicine East Norfolk Chest Clinic.

South-East Metropolitan Regional Hospital Board:

ELWELL, H. V. W., M.A. Camb., L.R.C.P., D.P.M.: asst. psychiatrist Hailsham group of hospitals.
GOLEBIOWSKI, A. K., MED. DIP. Lwow: asst. chest physician, Preston Hall group of hospitals.
MESTER, A. J., M.D. Cracow: asst. physician (geriatrics), Greenwich and Deptford group of hospitals.
ORCHARD, N. P., M.D. Lond.: consultant pathologist, Dartford group of hospitals.
WILSON, K. L., M.A. Camb., F.R.C.S., D.L.O.: consultant E.N.T. surgeon, Greenwich, Deptford, Woolwich and Lewisham group of hospitals.

Colonial Service:

BLAND, R. H., M.D. Dubl., M.R.C.P.I.: D.M.S., eastern region, Nigeria.
BOOKLESS, D. W., M.B. Edin.: M.O., Fiji.
CARROLL, D. S., M.R.C.S.: M.O., Barbados.
CHISWELL, D. A., L.R.C.P.: resident M.O. (interne), Kenya.
FLETCHER, G. H., M.B. Lpool: M.O. (Silicosis Bureau), Northern Rhodesia.
GOLIGHTLY, D. L., M.B. Durh.: M.O., Northern Rhodesia.
HARBEN, E. F., M.B. Madras: M.O., British Honduras.
IRWIN, D. B., M.D. Lond., M.R.C.P.: physician specialist, General Hospital, Barbados.
JAMES, S. T., M.B. Wales: M.O., Federation of Malaya.
JOLLY, T. G., M.B. Belf.: M.O., Fiji.
JONES, S. H. O., M.B. Manc., D.T.M. & H.: D.M.S., Gambia.
KNIGHT, ELLEN, M.R.C.S.: M.O., Tanganyika.
MAYCOCK, HELEN, M.R.C.S., D.C.P.: pathologist, Federation of Malaya.
PRAG, I. I., M.B., D.P.H.: M.O., Jamaica.
REES, W. H., M.R.C.S.: M.O., Fiji.
TARR, L. H., M.B.: M.O., Federation of Malaya.
TERRELL, J. D., M.B. Glasg.: M.O., Federation of Malaya.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

OPPORTUNITY AND THE UNIVERSITIES *

G. W. PICKERING
M.A., M.B. Camb., M.D. Ghent, F.R.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF LONDON, AT ST. MARY'S HOSPITAL

IF life is a game—and I believe that those who enjoy ife, and who contribute most to the happiness of their fellows, regard it as such—then an important component of the art of living is the recognition and use of opportunity. For opportunity means that circumstances have arisen which first make a desirable goal attainable. The recognition and use of opportunity are behind every successful enterprise, whether it be the hoeing of weeds, the sailing of a boat, the climbing of a mountain, a business deal, an act of diplomacy, or the winning of a battle. That great experimental scientist, Louis Pasteur, is reputed to have said: "Opportunity comes to the prepared mind." Small men often dismiss a great achievement as a piece of luck, and so it may be; but much more often it is the culmination of hard work and hard thinking, which has prepared the mind for the opportunity presented to it.

CLINICAL SCIENCE

There are, of course, many opportunities presented to the universities in the field of medicine; but, to my mind, the most important and the most timely is the development of the teaching of clinical science. This opportunity has long been evident and was repeatedly emphasised by my teacher and friend, the late Sir Thomas Lewis, who devoted the Huxley lecture given at Birmingham in 1935 to the subject of Clinical Science within the University. During the seventeen years that have since elapsed, the progress of scientific knowledge and the perfection of scientific method on the one hand, and the establishment of the National Health Service on the other, only emphasise the desirability of exploiting this opportunity fully without delay.

Clinical science includes all aspects of the scientific study of disease in man. It must use, and does use, the knowledge and methods of other biological sciences, such as physiology, anatomy, biochemistry, pharmacology, bacteriology, and pathology. But there has been, and is, a body of opinion that considers that these branches of science are alone of importance to the advancement of medicine and that clinical science is an applied science, in that it merely uses knowledge derived from animal experiment and applies it directly to the recognition, understanding, prevention, and treatment of disease in man. It is not my purpose to belittle the importance of these branches of biological science. No-one with any knowledge of the history of medicine or with an elementary sense of justice can deny the importance of the contributions that they have made or will make. They have won their place in the world of science, and in the universities, and their position if it needed defending would find an ardent champion in me. What I want to emphasise is that if we are to see the full fruits of the efforts of science to prevent and cure disease we require an attack all along the line, and that clinical science must win a place in the world of science, and in the universities, equal and not inferior to those of the other branches. For after all, from the point of view of the community, all this expenditure of human effort and of money is justified in so far as it alleviates human suffering. Any work which seeks to elucidate the cause of disease, the mechanism of disease, the cure of disease, or the prevention of disease, must begin and end with observations on man, whatever the intermediate steps may be.

All this, you may say, is obvious enough. What is not so obvious, or at any rate is not so clearly borne out by work that has already been done, or by opinions commonly expressed, is that man is a species that in many respects is quite unlike any species kept in cages and subject to the kinds of experiments that can be made by any discipline other than clinical science. He is more or less omnivorous, and his diet varies widely, from the tapioca, maize, and sweet potatoes of the African native, to the seal-meat of the primitive Eskimo, and the vitamins, carbohydrates, proteins, fats, and antibiotics of the North American civilisation. He becomes addicted to alcohol, tobacco, narcotics, and hypnotics. He is exposed to a variety of industrial poisons and hazards. He is about to expose himself to speeds exceeding that of sound, and perhaps, unless he can be prevented, to radioactive emanations, the effects of which we dimly perceive to be immense. Finally, and above all, man is possessed, to an exceptional degree, of that peculiar property, the mind, with its fears, desires, loves, and hates interwoven with the pattern of conditioned behaviour that is built up from the moment of his birth until the time of his death.

I need not remind a university of the importance of the mind, since it is in its exercise that the justification of a university lies. But I think I should emphasise how little we know still of its inner workings. I can go further and state that we still know practically nothing of the rôle it plays, if any, in the cause of organic disease. There are, of course, ideas abroad, summed up in the term psychosomatic medicine, which suggest that many diseases whose expression is organic are due to diseases of the mind. But with few exceptions the evidence is dangerously thin. May I also remind you that the greatest threat to the future welfare of mankind, war, is an expression of the mind of man, particularly of the behaviour of masses or crowds, and their relationships to individuals. Many people nowadays are alive to the threat which hangs over the whole of mankind. They recognise that man's knowledge of and control of physical agencies has far outstripped his knowledge and control of mankind. This is not surprising when the place of the scientific study of man is still to be fought out in that university course which would seem to have this as its focus—namely, the medical curriculum.

PRESENT LIMITATIONS

The importance of science to the practice of medicine needs no emphasis. The limitations imposed on the practitioner are the limitations of exact knowledge. Since I began the study of medicine, the power to heal and prevent disease that science has placed in the hands of the profession has been enormous. Effective treatment has been introduced for diabetes, for pernicious and other forms of anæmia, and for the infectious diseases with the notable exception of those due to viruses, while vitamin deficiencies have been almost eradicated in this country. Nowadays, the soldier is unlikely to die from typhoid, dysentery, or malaria, scourges that previously killed more troops than the enemy; and blood-transfusion and antibiotics have enormously decreased the death-rate from wounds. These advances have been made by team-work in which all branches of medical science have played a part, and all I wish to claim for clinical science is that it played the leading part in some of these advances, while none could have been made without it. But a review of these contributions of science reveals another important fact—namely, that discovery is not enough; it must be understood and used by the body of the profession if it is to bear fruit. The importance of the scientific attitude of the profession is well illustrated by the Pacific war. A notable factor in the Allied victory was that the Allies were better able to control malaria

---

* An address delivered at the inaugural session of the Medical School of the University of Birmingham on Oct. 6, 1952.

and dysentery, although mepacrine used for malaria was a German invention, and the sulphonamides used for dysentery were also of German origin.

Despite these advances, the doctor is still too often powerless, or his power is limited. Cancer, atheroma, hypertension, nephritis, Hodgkin's disease, the leukæmias, rheumatic fever, and rheumatoid arthritis are only some of the many diseases of which we do not know the exact cause or causes, which we cannot prevent, and for which we have no, or relatively ineffective, treatment. It seems unlikely that these diseases will prove to be simple examples of disturbed nutrition or invasion by microbes, and that their prevention and cure will be a simple consequence of a laboratory discovery. It seems almost certain that clinical science must play a major part in the attack, though, as I have emphasised, science must work as a team.

Take for example the problem of cancer. It seems that a number of chemical substances and certain viruses can transform the behaviour of certain cells so that they become cancerous. It seems also that the carcinogenetic agent may have had access to the body some years before the cancer develops. It seems therefore extremely probable that the factors which induce cancer in man will be identified only by scientific inquiry in man.

In the two subjects of great interest to me, animal experiment has helped to define the problem to be solved and to indicate clearly that the solution must come from clinical science. Thus hypertension can be produced in a variety of ways in the animal and it is possible that one of them may be an uncommon cause in man; but the solution of the vital problem, of essential hypertension, must come from man. Peptic ulcer can be produced in animals by inducing excess production of acid in the stomach, or by interfering with its neutralisation; the same mechanism probably holds for duodenal ulcer in man, but the inherited and environmental factors concerned only begin to be determined. Gastric ulcer is not, however, so caused, and here again we must depend on work on man.

Finally, I must mention psychological disturbances, the commonest cause of discharge from the Army in the last war, and a correspondingly large problem in peace. Psychology and its clinical counterpart, psychiatry, are branches of science as yet in their infancy with a meagre equipment of scientific method. These too, should participate in a general advance of clinical science. The body and the mind are not separate phenomena, and no serious scientific investigation on the one can afford to neglect the other.

THE OPPORTUNITY

I hope that these considerations will have convinced you of the importance of the scientific study of disease in man. In this country today we are presented with an opportunity of carrying out this study that would have seemed unbelievable seventeen years ago when Lewis gave his lecture. Most of the universities have established full-time professors with suitable assistants in the clinical subjects, including social medicine and pædiatrics and psychiatry. Moreover, the National Health Service has come into being, with its wealth of full-time hospital posts both senior and junior. Many men and women thus occupy posts with responsibility for the sick but in which remuneration is adequate, duties are limited, and tenure is secure—conditions that are eminently suitable for the pursuit of scientific knowledge, provided that these men and women have the urge, are prepared to use their leisure, and know how.

It is true that the whole-time posts in the health service exist primarily for the treatment of the sick; but it is also true that the man who is merely content to follow routine, and who makes no attempt to improve his own capacity to recognise disease, to understand it and to treat it, is a dull fellow, who is unlikely in the long run to render the best service. In the same way an institution in which no attempts are being made to advance knowledge is a dead, dull place, where the second-rate is all that is sought and attained. Thus even if we demand the efficient treatment of the sick, we are more likely to get it in an institution which seeks to advance knowledge and is, as it were, on its toes.

The catch in all this is that the vast number of men appointed to such posts do not know how to advance their subject, because they have had no training in scientific method as applied to the study of human disease. Let me give you a simple example. Over twenty years ago, severing the splanchnic nerves and removing adjacent sympathetic ganglia was introduced as a means of treatment of hypertension, and since that time many thousands of these operations have been performed. But to this day we cannot fully assess its value, because, although many series of patients subjected to this operation have been published, none have adequate controls. That is to say, no-one has taken a series of patients selected according to certain criteria and operated on some selected at random, leaving the remainder as controls, so that the effects of the operation on the course of the disease could be established once and for all time. This may sound an immoral proceeding, but it is in fact the best way to establish the value of a remedy whose effects are not at once and in all cases curative. To me it would seem a more immoral proceeding to use on a large scale a remedy without establishing whether it benefits or harms the patient. Obviously no-one introduces a remedy without believing it does good, but the history of medicine shows how often these beliefs are false. It is a man's duty to the profession and the community to prove whether his treatment is effective, and it is our duty as educators to see that the methods and standards of proof are known.

TEACHING OF SCIENTIFIC METHOD

For the fact is that the medical curriculum and the medical courses of most universities contain no organised teaching in clinical science, despite six years of intensive work by teachers and students. The first part of the curriculum does of course include examples of the scientific method as applied to the experimental animal and the test-tube, and certain aspects of normal behaviour. But in the second or clinical part of the curriculum the efforts of teachers and students are confined to learning the established discipline of medical practice. A few teachers try to teach scientific method during the clinical course; but the teacher knows and the student knows that his curriculum is overcrowded, and that he will not be examined in scientific method in his final examination. The discipline of medical practice cannot be dispensed with in the medical curriculum, but it is scarcely a sufficient object by itself for university education. As the Dean of Harvard said at a Harvard dinner which I attended: "I tell my students that in ten years' time half of what you are taught will have been shown to be wrong, and the trouble is that neither I nor any of your teachers know which half."

There are some who would say that scientific method is adequately taught in the preclinical curriculum and there is no necessity for it in the second or clinical part, which should be concerned solely with the art of medicine. This would be a just argument if all or even most doctors were going to be physiologists, biochemists, or anatomists, or were going to work in laboratories. But they are dealing with a very different kind of material. In this connection may be quoted a comment from the Cambridge report on "University Education and Business" (1945), the report of a Committee which included Sir Frederick Bartlett:

"The view that a University course should not be closely related to a man's ultimate career, but should be a general education in non-vocational subjects, is open to various interpretations. If it is meant that a University course should not consist merely of specific instruction designed for earning one's living, then no objection can be taken to it. If, on the other hand, the statement is interpreted to mean that a man is best prepared for life by reading subjects wholly unconnected with his career, then a good many objections can be taken to it. Such an interpretation depends ultimately on the assumption that habits of thought are transferable from one subject to another, but there is nothing in experimental psychology to suggest that such transfer will take place automatically. Any subject can be used as a means of training and developing the intelligence, and when intelligence has been developed by exercise it will be a better instrument for studying other subjects. This, however, is not the same as saying that the clarity in thought attained in one subject is directly transferable to another. In order to secure clarity the ideas involved must be easily manipulated, and an early acquaintance with these ideas is a great aid to proficiency. Further, if the subject is one for which the student has special interest he will more readily advance by using his innate ability unchecked by lack of interest in the subject matter."

WHAT, WHEN, AND WHOM

If, then, we are agreed that there should be some university teaching in clinical science, three questions remain, what to teach, when to teach, and whom to teach.

Lewis devoted much attention to the subject matter which he described by the term "theoretical teaching" to distinguish it from the "vocational teaching" of the craft. I dislike the term theoretical since it seems to stress hypothesis, which in another place Lewis described as "the heart which no man of right purpose wears willingly upon his sleeve." I have become more and more impressed with the validity of Karl Pearson's dictum that "the true aim of the teacher should be to impart an appreciation of method rather than a knowledge of facts." Again, to quote Barclay's *Apology*, "He that desireth to acquire any art or science, seeketh first those means by which that art or science is obtained." Disease in man poses problems which require the use of special methods to elicit an answer, and I think that the teacher should lay special stress upon these methods, their usefulness, and their sources of error. It would seem to me extremely probable that the methods expounded by Fisher in his *Design of Experiments* will find special application in the field of clinical science. This has already become clear in the clinical trial of new remedies, a method of therapeutic experiment which has in a brief space of time yielded conclusive and exact evidence of what may be expected of the antibiotics used singly or in combination and in defined dosage in specific types of disease of given severity. It is clear that the whole field of therapeutics needs an overhaul by the use of these methods by which we shall learn which of the old remedies are worth retaining and which should be discarded. But the whole field is vast and the science is young. At this stage methods of inquiry are usually borrowed from other subjects. But in the future, as the science grows, it will develop methods of its own to elucidate its own problems. No doubt different teachers will deal with different aspects. Out of them will come some well-defined course or courses with an accompanying textbook. But that lies in the future.

Lewis had in mind that the teaching of clinical science should form part of the undergraduate curriculum, some teaching being given to all students, and special attention being given to those with unusual ability and interest. I have tried to do something along these lines, but not enough. I have come to doubt whether such teaching reaches the average student, partly because he is not innately interested in discovery and exact knowledge, and partly because the medical curriculum is so overcrowded that he is chiefly obsessed with the task of memorising, and so appreciates the dogmatic teacher who presents him with material which can be reproduced in the form of an answer to an examination question. I think the most profitable step would be to arrange a short course for the abler students who elect to take it in the time which can be spared from the other duties of the undergraduate course. But I think ultimately it will be desirable to arrange a course, with full practical classes leading to an honours degree, for graduate students. Eventually, we might hope that such a course would have been taken by most of the staffs of the university clinical departments, and by the holders of senior posts in the hospital service. Such a course would economise men's time, since it would be given only to those able enough and interested enough to profit by it. That such courses would immensely improve the standard of thought and investigation into human disease is strongly supported by experience. There can be no doubt that physiology and biochemistry would never have made the progress that they have without the second part of the natural sciences tripos at Cambridge, the honours school of physiology at Oxford, and the honours B.SC. courses of other universities. Many universities are suitable for the development of such honours courses, but I can think of few with a staff more suited by virtue of their energy and intellect to carry out such a project successfully than the University of Birmingham.

OBJECTIONS

You may feel that the effect of what I am advocating is more and more research, when already none of us can keep abreast with the periodicals which multiply and divide until our medical libraries can scarcely contain the ever-increasing flood that descends upon them. The volume of publication is due to other causes, mainly the uncritical assessment of men by the weight of papers they have written. A body of men educated in scientific method and standards of criticism would result not in more but in less publication, not in more but in better research. Much of the work now published is badly conceived, badly executed, and inconclusive or misleading. One of the major causes of this is that there has been no serious attempt by our universities to educate men in scientific method and standards of criticism in the field of human disease.

Some feel, too, that scientific work on patients is not in their best interests, and they may doubt whether an improvement in the scientific standard of clinical investigation may not be accompanied by a corresponding fall in the ethical behaviour of the doctor towards his patient. It is perfectly true that the doctor who is interested in scientific proof has an interest and an objective other than what he regards as the best interests of each individual for the time being. And it is therefore important that any courses in clinical science should emphasise the importance of the ethical issues. But the fact is that there is a great deal of muddled thinking on this point. Take for example the treatment of hæmatemesis. Some doctors believe in starving their patients, some in feeding them, some in liberal transfusion, some in limited transfusion, some in operating on all cases, others in operating on selected cases, and yet others in operating on none. Each of these doctors, following his belief, or prejudice, believes when he prescribes his treatment that he is acting in the best interests of his patient. Yet there can be no doubt that some of these treatments have a much higher mortality than others, and that many patients die who should not die if the merits of the rival methods of treatment had been properly established by scientific standards. As I have said before, the chief limitation on the power of the doctor to help his patient is ignorance. The cure for ignorance is experience, and there can be no doubt whatsoever that in the long run the scientific method is by far the most economical use of experience both in terms of human effort and in terms of wastage of life by dangerous or ineffective therapy. Professional standards and scientific standards may seem at times to be in conflict, but in the long run they are but two aspects of the same problem—how the doctor can best help his patient.

OPPORTUNITY—OR UNIFORMITY ?

Finally, I would like to emphasise that a new suggestion for the improvement of medical education carries with it a real danger for the student. Nearly all individuals and committees that have seriously considered the curriculum agree that it is too full, and that the students' load should be lightened. Yet when these recommendations come to be implemented, the reverse happens and the load is increased. We are now witnessing a tragic instance of this kind. The medical faculties of our universities owe their present comfortable circumstances to the recommendations of the Goodenough Committee. Another of the recommendations of this committee was that the duration and content of the medical curriculum should be reduced, and such importance was attached to this recommendation that the committee thought that it might well be made a condition for the increased grants for medical education. Unfortunately, this reduction in the curriculum has never been made, and, where the university courses have been revised, they have been made longer and more rigorous.

Nowadays in some universities a boy entering medicine must look forward to a minimum of six years' undergraduate training, one year's house-appointments, and two years' military training—a total of nine years before he becomes a free agent. Add to that the recommendations of the Royal Colleges of five more years' training, much of it prescribed in detail, before he can become a specialist, and we have a total of fourteen years of training rigorously prescribed for the intending specialist.

Each of these recent additions, or proposed additions, to the compulsory requirements, looks innocent enough by itself: one, the compulsory year of house-appointments, is by general agreement necessary, and one, military service, depends on circumstances outside the control of those responsible for education. But when we look at the total sum we can quickly see how catastrophic the effects will be. If we wished to stereotype medicine, to ensure that we should never again have our James Mackenzies and our Thomas Lewis's I cannot imagine a more effective method. For these fourteen years are the formative years, the years of ideas and initiative in which the individual begins to make his contributions, if he is to make them at all. Real progress comes from the new approach, from the man who in his experience and outlook is different from the majority. We cannot legislate for such men, but we can ensure that never again shall they have the opportunity to acquire that unexpected and unusual outlook and exercise it effectively in medicine; and this is precisely what we seem to be trying to do.

Whenever I consider these increases in compulsory requirements I find myself so astonished that I am tempted to wonder if it is I or those who take the opposite view that are mad. I suspect there are many like myself who are dismayed, but we have allowed, or are allowing, small groups of zealous bigoted men to undermine our position. If we have the interests of medicine and of the student sincerely at heart, we must realise what we are doing and allowing to be done, and try to retrieve the lost ground, both in the undergraduate curriculum and in the postgraduate period. But we must act, for the sands are running out.

I see all this not as the machinations of wicked men, nor necessarily those of stupid men, but as part of a disease of society which might be named compulsory uniformity. It is not a new disease, but it has found an unusually susceptible population, and the organism has acquired exceptional virulence, in this age of reasoned planning. The facts to which I have drawn attention are its manifestations in the domain of medical education. I regard this as a serious disease and one which our society must learn to recognise if it is to eradicate it before it is too late. I would therefore like to end by saying that while I advocate the teaching by our universities of scientific method as applied to human disease, I would not see it added as a compulsory requirement to the undergraduate curriculum, or as a compulsory postgraduate requirement for any post. If in the future I do advocate these things, you will know that I, too, have fallen a victim to this fell disease.

THE EFFECT OF HEXAMETHONIUM BROMIDE ON THE CARDIAC OUTPUT AND PULMONARY CIRCULATION

WITH the reintroduction of the tetraethylammonium compounds in 1946 by Acheson and Moe, there has been a renewal of interest in drugs that block the autonomic ganglia, and in the last two years the methonium compounds have been used therapeutically as hypotensive agents. The methonium compounds have the advantage, over the tetraethylammonium compounds, of smaller side-effects and longer action. Paton (1951) has demonstrated that they act by "competitive block" of the autonomic ganglia without affecting the release of acetylcholine from the preganglionic nerve-endings. He has also shown that in lowering blood-pressure these compounds act by relaxing autonomic arteriolar tone

TABLE I—RESULTS OF INTRAVENOUS INJECTION OF HEXAMETHONIUM BROMIDE

rather than by a direct action on blood-vessels. The value of postural hypotension in the treatment of hypertensive patients with these drugs was described by Restall and Smirk (1950), who recently (1952) demonstrated that this postural or gravitational hypotension was due to "decrease in the capacity of vessel walls of dependent parts to contract and thereby resist gravity-pressure dilatation." They showed that postural hypotension could be overcome by immersing the subject in water up to heart level.

The present investigation was undertaken to determine the effect of hexamethonium bromide on the cardiovascular system, with special reference to the changes in cardiac output and pulmonary circulation.

METHOD

Fourteen patients with severe hypertension from different causes were studied. None was in congestive failure at the time of the investigation, but all had clinical complications of their hypertension indicating a need for hexamethonium therapy (McMichael 1952).

Cardiac outputs were determined by the direct Fick principle with the method described by McMichael and Sharpey-Schafer (1944), mixed venous samples being obtained from the right atrium or ventricle by cardiac catheterisation.

In four patients the effects on cardiac output and right ventricular pressures were observed after the injection of hexamethonium bromide through the cardiac catheter. The dose used was that previously found to produce a satisfactory fall in systemic blood-pressure. Estimations of cardiac output, simultaneous right ventricular tracings (Bayliss et al. 1950), and brachial arterial tracings were obtained during a control period and after the injection of the drug when the blood-pressure had become steady at its new level. The patients were kept in a horizontal position during the period of observation.

In ten patients the hexamethonium bromide was given by subcutaneous injection and the postural effects were studied. Cardiac outputs were estimated from mixed venous samples obtained from the right atrium during a control period in the horizontal position and subsequently with the patient tilted 30°–45° feet downwards. The investigations were repeated 30 minutes after the subcutaneous injection of hexamethonium bromide. The dose used gave a substantial fall in blood-pressure when the patient was in the feet-down position, and was based on the result of a test on the previous day. Auscultatory blood-pressure measurements were taken.

The arterial oxygen saturation was determined with an ear oximeter (Wood 1950), with which the changing concentration of Evans Blue dye passing through the warm ear was recorded by photographing the light spot of the galvanometer on the falling plate of a Cambridge electrocardiographic camera (fig. 3). Dye time-concentration curves were thus obtained after the injection of Evans Blue (1% solution) through the cardiac catheter directly into the right atrium (Gilmore et al.) in the vertical and horizontal positions before and after the injection of hexamethonium bromide. From these curves the mean circulation-time from heart to ear was derived. The cardiac output (simultaneously estimated

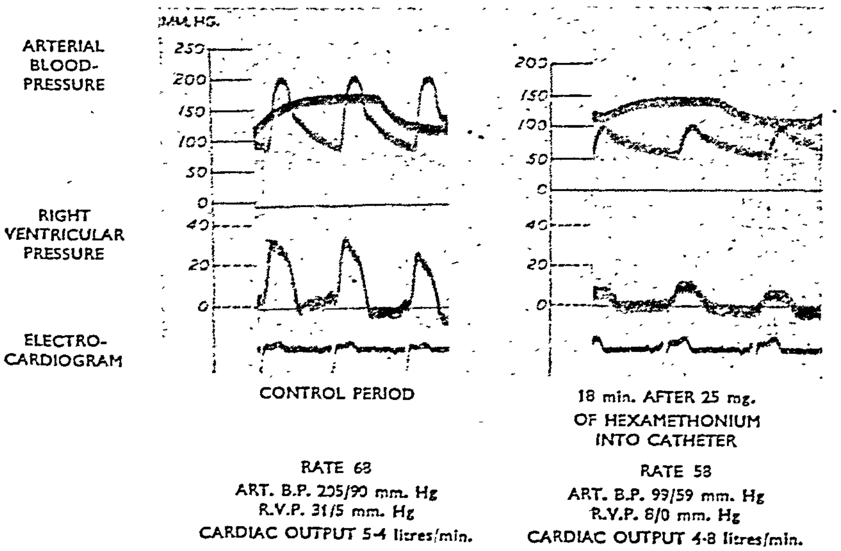

Fig. 2—As fig. 1.

In the tilted position the mean circulation-time was greatly prolonged after hexamethonium, indicating an increase in the cardiopulmonary blood volume.

It is concluded that hexamethonium prevents the normal reduction in the lung vascular capacity which occurs in the feet-down position. This, together with the fall in the pulmonary-artery pressure, implies that the pulmonary vessels have a vasoconstrictor nervous mechanism which is blocked by hexamethonium compounds.

We should like to express our thanks to Dr. M. E. Etheridge, Dr. Brenda Morrison, Dr. L. W. Ritzmann, and Dr. N. J. Selverstone for help in making these observations, and to Dr. R. Steiner for radiological help. Part of the expenses were met by a grant from May & Baker Ltd, who also supplied the drug.

THE MANAGEMENT OF CŒLIAC DISEASE

WILFRID SHELDON
M.D. Lond., F.R.C.P.
PHYSICIAN TO THE CHILDREN'S DEPARTMENT, KING'S COLLEGE HOSPITAL; PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON

DAVID LAWSON
M.D. Camb., M.R.C.P.
MEDICAL REGISTRAR, THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET

FOR many years there has been controversy over the relative importance of carbohydrate and fat in the production of cœliac disease. In his original description Gee (1888) advised a trial of cream and fresh butter, while recognising that the amount of farinaceous food must be small, and Howland (1921) and Haas (1938) based their dietetic management on the exclusion of starches. In this country Still (1918) and Parsons (1929), although recommending a reduction of starch, held a failure of fat-absorption to be the chief difficulty and advised that both fat and carbohydrate should be severely curtailed, leaving protein as the main source of nourishment. A diet of this type remained in vogue until after the late war, and was reflected in the special rations allowed for cœliac children on production of an analysis showing a high excretion of fat in the fæces. Whatever else it achieved, this type of diet undoubtedly led to an insufficient calorie intake over long periods, and contributed to the long stay in hospital of many of these children, while it was all too common an experience that progress towards recovery was tardy in the extreme.

In recent years fat-balance studies have shown that isolated analyses of fæcal fat give no true indication of the amount of fat that is being absorbed; and that cœliac children can absorb more than half their dietary fat even when the disease is severe. The wisdom of excluding fat from the diet and of thus denying them the opportunity of absorbing any fat at all is therefore open to question. Nutrition depends on what is absorbed rather than what is voided, and to base a dietary régime on stool analysis errs in the direction of treating the stools rather than the patient. It might be more reasonable to argue that, if fat-absorption is below normal, a greater head of fat should be supplied to make good the wastage in the stools.

Since 1947 we have treated 64 children with cœliac disease, and our results form the basis of this communication.

STARCH AND GLUTEN

One of us has reported that the entire exclusion of starchy food from the diet led to a significant increase in fat-absorption (Sheldon 1949), and this led to treatment with a diet in which protein and fat were given in normal amounts but carbohydrate was restricted to simple sugars. The children improved rapidly: not only was there a swift gain in weight and a steady though less spectacular gain in height but their perverse and unhappy behaviour quickly changed to a happy demeanour. The beneficial effect on fat-absorption of withdrawing starch from the diet has since been confirmed by Lowe et al. (1951).

Meanwhile in Holland Dicke (1950) and Weijers and van de Kamer (1950) observed that both wheat flour and rye flour exert a deleterious effect upon fat-absorption in children with cœliac disease, but that this is due to the protein component (gluten) and that, if the gluten of wheat flour is removed, the remainder, consisting of wheat starch, is well tolerated.

We have confirmed this observation at The Hospital for Sick Children, Great Ormond Street, and it has also been confirmed by Anderson et al (1952). These workers correctly point out that the benefit accorded to children with cœliac disease by the exclusion of starch is not so much due to the strict removal of all starch as to the fact that its removal from the diet entails the exclusion of wheat gluten. The precise manner in which gluten operates adversely on children with cœliac disease remains to be elucidated.

The present position concerning our dietetic management of these children may be summed up by saying that the objective is a diet from which gluten is completely excluded but which is in other respects normal. How long a child with cœliac disease should remain on such a diet has not yet been determined, but to base a return to gluten simply on a clinical assessment of well-being is in our experience insufficient. All too often, when gluten is reintroduced the rate of growth promptly slows, although if treatment has persisted for several months the complete picture of cœliac disease does not necessarily reappear. Thus if the child has already reached school age he may continue happily at school, maintain a fair appetite, and perhaps only pass one or two rather bulky motions each day. As at this stage the children are probably attending hospital only three or four times a year, the fact that the return to gluten has checked growth may escape notice for several months. We shall come back to this point later when describing our method of following up these children, with particular attention to recording their heights and weights, from which it is hoped to find a means, more precise than clinical assessment, of deciding when a diet devoid of gluten can be abandoned. Perhaps such a diet should be persisted with throughout the years of growth.

Although the removal of gluten from the diet is essential it would be incorrect to suggest that this is all that need be done for the dietetic management of a young child severely ill with cœliac disease. Several weeks of careful, experienced, and persuasive nursing may be required before the child can accept a full gluten-free diet, the ingredients of which must be gradually added, with many a rebuff, to a diet which at the beginning is much simpler; there may have to be an early phase in which fat is reduced and starchy foods are entirely withheld.

It is also necessary for the physician to become "caloric-conscious" and to know the energy value of the diet he has prescribed. A good diet can easily fail to enable a child with cœliac disease to gain weight unless sufficient food is being ingested daily, and we have been surprised at the high calorie intake that some of our patients have required. As soon as the child has started taking his new diet satisfactorily, the calorie intake should be steadily increased until the weight begins to rise: this can be done either by increasing the amounts at each meal, or, if the child seems already to have reached satiety, the calorie intake can be augmented by the addition of glucose. In some of our cases the intake of glucose has gradually risen to 4 oz. a day. The accompanying table shows the number of calories per pound body-weight that has been needed to get a satisfactory weight gain. We have used not the expected but the actual body-weight, and, as with marasmic infants, the more wasted the patient the higher must be the calorie intake per lb. of body-weight.

Daily calorie intake per lb. body-weight	40–49	50–59	60–69	70–79	80–89	90–99	100 or more
No. of cases ..	4	8	15	12	11	4	2

It will be seen that the great majority of the children needed 60–90 calories per lb. body-weight per day. Such a high calorie intake would be very difficult to achieve if fat, with its high calorie value, were excluded from the diet.

ANÆMIA AND INFECTION

The importance of dealing with anæmia and infection must be pointed out, for otherwise dietetic treatment is bound to be disappointing.

Anæmia is common in children with cœliac disease and is usually hypochromic. If the hæmoglobin is above about 65%, the anæmia can be slowly rectified by adding iron to the diet; but, if the anæmia is more severe, it is better to give a blood-transfusion. We have transfused blood in nearly a quarter of our cases. Occasionally the anæmia is megaloblastic; it will then respond quickly to a fortnight's course of folic acid 5 mg. thrice daily. This type of anæmia occurred in 5 of our cases. Not uncommonly the severely ill child with cœliac disease combines anæmia with œdema, usually in the lower extremities; occasionally ascites is present, and usually such children have a lowered blood-protein level. A blood-transfusion will serve the added purpose of raising the blood-proteins, or this may be accomplished by a transfusion of plasma. It is permissible to hope that, in the future, children suspected of having cœliac disease will be given a trial of a gluten-free diet while their disease is still in its early stage, and will be restored towards health before their condition has sunk so low as to require transfusions of blood or plasma.

Infection.—Cœliac disease uncomplicated by infection is an afebrile illness with a normal erythrocyte-sedimentation rate. Intercurrent infections, usually of the upper respiratory passages, arise easily in these weak children, and almost invariably lead to an exacerbation of the cœliac symptoms, which require prompt recognition and treatment. It is equally essential to recognise and treat any focus of persistent infection, whether in the gums, urine, or throat; otherwise a satisfactory response to dietetic management cannot be expected.

DIET

The following description of our dietetic management begins with a young child—say about two years of age—already severely ill with cœliac disease, greatly wasted, and with an appetite capricious to a degree. To such a child we offer four foods: skimmed milk, 'Prosol,' * glucose, and banana purée. The prosol is
by adding 1 drachm of powder to 1 oz. of wat
prosol and skimmed milk being given togethe
proportions. The mixture is sweetened by
teaspoonful of glucose to every 2 oz. Feeds
every four hours, either five or six feeds in tw
hours, and usually 8 oz. at each feed.

Banana purée is given either separately or m
some of the milk feed, starting with half a ban
and increasing to a whole banana. Not inf
the child dislikes the banana, in which case it i
If the stools remain frequent and watery '
may be used to help consolidate them, 2 or 3
fuls being added to each 8-oz. feed until t
become formed.

Changes from the initial diet begin as soon as
evinces interest and pleasure in feeding.
additions consist of minced chicken, egg cus
biscuits made from soya flour and spread wi

departments be expected to reach uniformit
end-points of the various stages.

---

* Prosol (Trufood Ltd.) is a dried skimmed milk with added protein. When reconstituted by adding 1 drachm of powder to 1 oz. of water, it has the composition: protein 7·75%, fat 0·125%, and carbohydrate 3·4%.

† Arobon (Nesfoods Ltd.) is prepared from the carol
virtues being due to its lignin, pectin, and heav
content.

When the child leaves hospital, the principles of a gluten-free diet are explained to the mother, and she is given the following instructions, which include a list of the foods that contain gluten and must be avoided, while indicating a few of the foods which are in fact gluten-free but which, we find, are often withheld unless their harmlessness is mentioned:

"Your child may have an entirely normal diet except that nothing may be given which is made from wheat flour or rye flour. As a substitute for flour, pure wheat starch, as supplied by the Energen Foods Co. Ltd., Bridge Road, Willesden, London, N.W.10, may be used in unlimited quantities. It may be found useful to supplement the diet with soya flour and cornflour, which are also harmless. Potatoes may also be given in normal quantities.

"The following are some examples of foods in common use which may NOT be given as they are made from or may contain wheat or rye flour:

Bread
Biscuits
Cakes
Cream of wheat
Doughnuts
Energen rolls
'Grape Nuts'
Ice-cream (commercial)
Macaroni
Malted milk
Noodles
'Ovaltine'
'Procea' bread
'Proferin' rolls
Packet cake and pudding mixture
Packet soups and gravy browning
Pastry mix
Patent foods
'Puffed Wheat'
Paste (fish or meat)
Rusks
'Ry-Vita'
Semolina
Spaghetti
'Shredded Wheat'
Sweets of unknown composition
Sauces (commercial)
Salad cream
Sausages
Tinned soups and meats
Vermicelli
'Vita Wheat'
'Weetabix'

"No breakfast cereal foods other than those specifically recommended should be given. The following, however, are harmless:

'Cornflakes'
'Puffed Rice'
'Rice Krispies'

"Gravies and sauces may be thickened with pure wheat starch or cornflour, but not with ordinary flour. Ordinary household cocoa may be given but not proprietary preparations (such as ovaltine).

"*NOTE.*—Do not give any other foods unless you are quite sure that they are entirely free of wheat or rye flour."

We also supply the mother with the following recipes for the preparation of bread, cakes, and biscuits:

GLUTEN-FREE RECIPES

Wheat-starch Loaf

½ lb. pure wheat starch
2 oz. sugar
2 oz. margarine
4 teaspoonfuls baking-powder
Milk as required

Sieve the dry ingredients into a basin, rub in the margarine, and mix in enough warm milk to make a batter consistency. Mix lightly and pour into a greased tin. Bake in a quick oven for 10 min., then reduce to moderate heat for a further 30 min.

Soya Wheat-starch Loaf

2 oz. soya flour
7 oz. pure wheat starch
2 oz. fat
5 teaspoonfuls baking-powder
1 teaspoonful sugar
½ teaspoonful salt
6 oz. milk
6 oz. water

Method as for wheat-starch loaf

Wheat-starch Cake

½ lb. pure wheat starch
4 oz. sugar
4 oz. margarine
1 teaspoonful salt
3 teaspoonfuls baking-powder
4 oz. milk
1 egg (optional)
Flavour with coconut, dates, or chocolate

Sieve the dry ingredients into a basin, rub in the margarine, and mix in enough milk to make a soft dough. Knead lightly and turn into a well-greased shallow tin. Bake about 30 min. in a hot oven (400°F, Reg. 7)

Small Cakes

6 oz. pure wheat starch
4 oz. margarine
4 oz. sugar
1 egg
1 heaped teaspoonful baking-powder
Grated orange rind

Cream together margarine and sugar, add the egg and orange rind, and then the flour. Cook for about half an hour in a moderate oven (300°F, Reg. 5). Makes eighteen small cakes

Wheat-starch, Soya-flour, and Rice-flour Cake

4 oz. rice flour
4 oz. pure wheat starch
2 oz. soya flour
4 oz. castor sugar
4 oz. margarine
1 egg
6 oz. milk
1 oz. sultanas
4 teaspoonfuls baking-powder

Sieve the dry ingredients into a basin, rub in the margarine, and mix in enough milk to make a soft dough. Knead lightly and turn into a well-greased tin. Put in a quick oven (400°F, Reg. 7) for 5 min., then reduce heat to 300°F (Reg. 5) and bake for a further 55 min.

Soya Wheat-starch Biscuits

3 oz. soya flour
3 oz. pure wheat starch
3 oz. margarine
3 oz. sugar
1 egg
Vanilla or orange flavouring

Cream together margarine and sugar, add the egg, soya flour, and pure wheat starch, and knead into a stiff dough. Roll out ¼ in. thick and bake in a moderate oven for 10 min.

Soya Biscuits

Follow the recipe for soya wheat-starch biscuits, using 6 oz. of soya flour and omitting wheat starch.

RATIONING

The special rations for children with cœliac disease, introduced during the late war reflected the opinion that fat was injurious and that protein should be the main source of energy. In the acute phase of cœliac disease five extra meat rations were allowed, and the fat ration was cancelled: in the "convalescent" stage the fat ration was restored, but only two extra meat rations were allowed.

When, in the design of the gluten-free diet, pure wheat starch was substituted for the gluten-containing flours of the normal dietary, it was found impossible to make a loaf or a cake which would hold together without the use of eggs or fat. This presented no great obstacle to the preparation of such foods while the children were in hospital, but it was soon found that, after discharge on a gluten-free diet, the cœliac in the home was consuming most of the family's slender resources of eggs and fat. The Ministry of Food have therefore authorised the issue, to children undergoing treatment for cœliac disease with a gluten-free diet, of one extra fat ration, and one priority egg allowance, in return for which one of the two extra meat rations hitherto allowed in the "convalescent" stage is surrendered. This alteration in rationing has been found adequate for the use of wheat starch.

PROGNOSIS

There have always been wide divergences in the prognosis of cœliac disease given by different observers.

Gee (1888) wrote "Death is a common end . . . even when it tends slowly to recovery they are left frail and stunted." Cheadle (1903) had seen 1 fatal case only. Still (1918), reporting on 41 cases, observed that 6 of the children had died (1 from pneumonia) and asked: "Is there ever complete recovery in the sense of attaining eventually average height and acquiring normal pubertal growth?" Howland (1921), however, describing a series of 30 cases treated by exclusion of polysaccharide from the diet without a death, observed: "They do not remain semi-invalids. Many become vigorous and strong, some even with no trace of dietary idiosyncrasies, sometimes with a digestion that must be treated with care." The experience of Parsons (1932) was that, in spite of careful treatment, progress towards recovery was always slow and intermittent, and it was his opinion that "Any definite retardation of growth always leaves it mark . . . and . . . the child never reaches normal height."

Andersen (1947) and Haas and Haas (1950) reported a high degree of success with a diet free from cereal starches, and the latter conclude that less than a fifth of the patients need more than two years' dieting. Their criteria of cure, however, do not seem strict enough, nor do they define normal growth.

The prognosis of cœliac disease was, before the late war, discussed clearly only in terms of mortality. Hardwick (1939), reviewing the published series, found an over-all mortality of 15% in 544 cases.

In the present series of 64 cases there has been 1 death from cœliac disease: a severely ill child died in tetany very shortly after admission and before treatment could be effective. Another child, who was doing well on a starch-free diet, was killed in a motor accident. It would seem that, under good conditions of care, mortality is approaching vanishing-point, and a different method of assessing results is required.

No technique of management is completely effective unless it allows the children to regain optimal growth as regards both height and weight. The ideal growth curve would start with a recovery phase in which tissues were being rebuilt and the growth lag was being made good; in this phase the rate of gain in weight would be abnormally high; when the optimal level was reached, the curve would flatten out toward a normal rate of gain.

On the starch-free (and incidentally gluten-free) diet this ideal curve was attained while the children were under our care in hospital, where they gained weight rapidly at gradients of 20–100 lb. a year; but in few cases was this curve continued after the children were discharged to their homes. In most cases a flattening in the gradient, before the optimum had been reached, coincided with discharge from hospital. Despite this lack of growth, however, the children nearly all remained free from symptoms in what passed for normal health, and grew slowly, while their parents were attempting either to maintain a starch-free diet at home or were being allowed to try relaxations of the diet. We suspected that this lack of growth was attributable to the great difficulty, both technical and economic, of giving at home a diet from which both the staple foods, bread and potatoes, were entirely excluded; but there seemed little to be done about it, short of admitting apparently well children to hospital and keeping them there indefinitely. Whenever one of these children became ill and was readmitted, the ideal curve was resumed once more upon the reinstitution of a strict starch-free diet.

The promise which starch-containing gluten-free diets offered of easier dietary maintenance at home led us, toward the end of 1951, to review all cases treated with starch-free diets since 1947. Of the 64 children in the series 2 have died, and we have lost touch with 3. Of the remaining 59, 25 who are now on a normal (gluten-containing) diet are in a state of health regarded by their parents as normal, and would pass without comment in a school environment; but a study of their growth pattern suggests that many would probably benefit from a gluten-free diet. 15, whose development was clearly unsatisfactory, although they too were broadly symptom-free while on a normal or partially starch-free diet, have in the last nine months been put on to a gluten-free diet, and all have since shown an increase in the weight gradient above normal rates of gain. The remaining 19 cases are more recent, and all the children have reached a gluten-free diet as a part of their initial management. In no case has the introduction of starch, free from gluten, interfered with the progress of the weight curve.

Both in children discharged on a gluten-free diet after initial treatment, and in those introduced to a gluten-free diet after a period at home on a "starch-free" or normal diet, there have sometimes been delays in response or periods of lack of growth. In the absence of infection or other intercurrent disease such failures have always been found, if careful enough investigation was made, to be attributable to the inclusion of a gluten-containing food in the diet; and normal growth has been resumed on the exclusion of the offending article. Although we have made no precise experiments to determine the effective threshold toxic dose of wheat gluten, it is within our experience that this is small. We have observed on several occasions that the relaxation of the diet to the extent of allowing one slice of toast a day (containing about 2 g. of gluten) checks growth.

The gluten-free diet is not difficult to give at home, nor is it expensive. The difficulties we have encountered are two:

(1) The presence of small quantities of wheat flour in a wide range of manufactured products not clearly of wheat-flour origin—e.g., ovaltine and 'Horlicks.'

(2) The difficulty of persuading parents that the diet must be rigidly adhered to even if experience shows them that relaxation of the diet brings in its train no dramatic return of symptoms. It must be explained to them that the ill effects may merely consist in a growth failure measurable only over several months.

Our technique of assessing progress, and of deciding in the future when gluten may safely be introduced, is as follows:

Individual weight and height curves are plotted on a chart, upon which are printed means and standard deviations of height and weight from ages 1 to 12 years. Increments in height are regarded as of even greater significance than increases in weight.

The initial rate of gain while the child is "catching up" will be faster than normal, but at some point within the normal range the growth curves will flatten out toward the normal gradient. It is particularly important that the diet should be strictly maintained for some months beyond this point, until the child has continued, from his optimal level, to grow steadily, and has thus provided personal standards of normality whereby his subsequent behaviour can be judged. When this stage has been reached, gluten-containing foods may be experimentally introduced, but it must be recognised that their failure to bring about an immediate clinical relapse is no proof that the sensitivity to gluten has passed. In most cases it will take three or four months for lack of growth, consequent on relaxation of the diet, to show itself.

The more closely we study the long-term growth charts of our patients the longer does it appear necessary to withhold gluten from the diet, but we are not yet in a position to say whether gluten should be excluded throughout the years of growth. There is, however, in our experience nothing incompatible with such a hypothesis. There is certainly no justification now for accepting anything short of optimal growth as evidence of success in treatment.

Many aspects of cœliac disease remain to be studied; but against the background of the conception of cœliac disease as a specific poisoning with certain cereal proteins, there is a rich field for precise metabolic investigation on the one hand, and on the other for therapeutic success with the simplest of weapons.

It is a pleasure to record the generous help we have received from Prof. A. C. Frazer and his department in Birmingham, and from Dr. W. W. Payne at Great Ormond Street throughout our investigations into this disease; to acknowledge the kindness of our colleagues who have made available to us their cœliac patients; to pay tribute to Miss Dillistone, the hospital's dietitian, who has followed so patiently the requirements of a changing technique; and to Sister Parcell for her nursing skill; and to express our thanks to the Ministry of Food for coöperation in making the experimental diet possible before a change in rationing was finally decided.

RELATIVE NOCTURNAL POLYURIA AS A FACTOR IN ENURESIS*

E. MacLean Poulton
D.M. Oxfd, M.R.C.P., D.P.H., D.C.H.
SENIOR PÆDIATRIC REGISTRAR, WHIPPS CROSS HOSPITAL, LONDON

This paper is based on the investigation of a consecutive series of 100 children with enuresis but without ascertainable organic disease. This investigation was made in 1950–51 at Whipps Cross Hospital, and its purpose was to lay bare any mechanical factors which might be responsible for the incontinence. The ages of the patients ranged from four to fourteen years: 18 children, fully continent of urine, served as controls.

Ström-Olsen (1950) has suggested that nocturnal enuresis in adults is often associated with hypersomnia; but excessively deep sleep cannot be the chief cause of the wetting in children, since continent children do not wake to pass urine but contain the total volume of urine excreted during the night and void it in one act in the morning. Further, the administration of copious drinks at 8 P.M. to a wardful of continent children has repeatedly produced wet beds in 10% of the occupants. The normal child is dry because the volume of urine he excretes during the night is less than the volume that his bladder will hold.

DIURNAL RHYTHM OF WATER EXCRETION

The first descriptions of the rhythm of excretion of urine were given by Roberts (1860) and Quincke (1877). Roberts stated that $4^1/_2$ times as much water was excreted by day as by night, and of the solid constituents of urine twice as much.

Simpson (1924) studied the rate of excretion of water in more detail, keeping the fluid intake constant. He found that the rate of excretion rose sharply at about 7 A.M. and dropped sharply in the evening at any time between 4 P.M. and 10 P.M. This rhythm, he claimed, was not affected either by darkness or by sleep. Borst and de Vries (1950) have described this rhythm more recently.

METHOD OF INVESTIGATION

The children, both enuretics and controls, were studied in the ward for six days each. The normal ward routine was followed, drinks being offered at meal-times, but further fluid being given if the child desired. The fluid intake was recorded.

During the daytime each child passed urine as desired, and the time, volume, and specific gravity were noted on each occasion. The greatest volume passed in one act, and the mean of all these volumes, served as two measures of the volume of urine that the bladder would comfortably hold.

During the night both the enuretics and the controls were woken every three hours and urged to void urine. A few children, who continued to wet despite this, were woken every two hours, so that all the urine excreted could be measured. The twenty-four hours of each day were divided into two periods of twelve hours each at 8 A.M. and 8 P.M. The mean volume excreted in each of these periods was recorded, and the day to night (D/N) ratio was calculated for each child.

FINDINGS

Controls

In the 18 normal children the volume of urine excreted by day was generally two or three times that excreted by night. The lowest D/N ratio was 1·8, and the ratio was independent of the age of the child. The mean volume in ounces of urine excreted in the twenty-four hours was not greater than twice the age in years plus 18 (or, in millilitres, sixty times the age in years plus 540). The mean volume in ounces passed by a normal child in one act was at least half his age in years (or, in millilitres, fifteen times his age in years). The greatest volume voided by a normal child in these conditions in one act was twice the mean volume.

For example, a normal child aged six years would at each act pass on the average 3 oz. but occasionally 6 oz. (180 ml.). His average excretion in the twenty-four hours would be less than 30 oz. (900 ml.), of which less than a third would be excreted during the night.

Enuretic Children

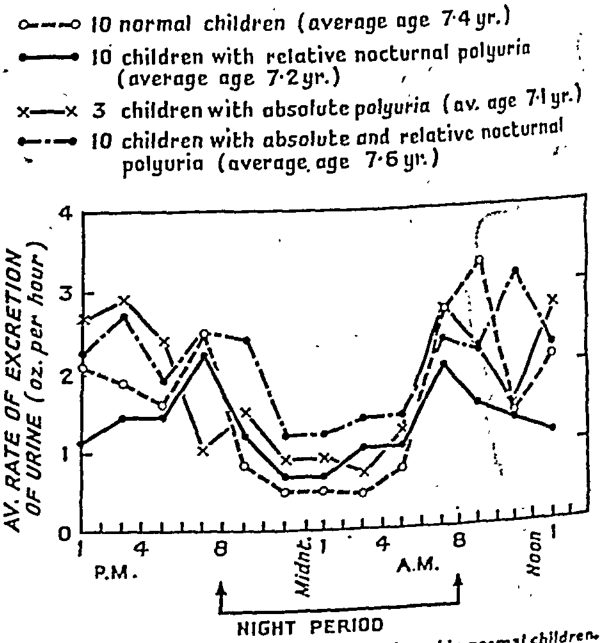
Of the 100 enuretic children, 69 were found to excrete an unduly large proportion of their urine by night, the D/N ratio being less than 1·8. I suggest this condition be called relative nocturnal polyuria. Among these 69 all degrees of severity were found, with D/N ratios varying from 1·8 (the lowest figure compatible with a normal diurnal rhythm) down to 1·0, at which figure there is no appreciable diurnal rhythm at all. In only 2 children was the D/N ratio less than 1·0, indicating a reversal of the diurnal rhythm as described by Batty (1948).

Of these 69 children with relative nocturnal polyuria 11 were found to be passing an abnormally high volume of urine in the twenty-four hours, and a further 5 children with a normal diurnal rhythm passed a similarly excessive amount of urine (absolute polyuria). In none of these children was there any albuminuria or glycosuria, and in all the urinary specific gravity was normal.

Excretory Rhythms Compared

The diurnal excretory rhythms found in normal children and in three groups of enuretic children are shown in the accompanying figure. The curves differ in degree rather than in type. In all of them there is an evening diuresis greatest at 7 P.M., followed by a decrease in excretion to a minimal figure about midnight. There is a morning diuresis starting at 5 A.M. and reaching a peak about 8 A.M. However, the minimal rate of excretion at night was considerably above the normal in all three groups of enuretic children.

The evening and morning peaks of diuresis explain the tendency for nocturnal incontinence to occur shortly after going to bed (Smellie 1949) and shortly before rising in the morning.



Diurnal rhythm of urinary excretion in enuretic and in normal children.

---

* Adapted from a thesis submitted to the University of Oxford for the degree of Doctor of Medicine.

SYMPTOMS OF RELATIVE NOCTURNAL POLYURIA

Of the 69 children with relative nocturnal polyuria all were wet at night, and only 14 were also incontinent by day. In these 14 children the nocturnal wetting was the more severe, the diurnal wetting occurring only when precipitancy of micturition prevented the child from reaching the lavatory in time.

Apart from nocturnal enuresis the most common symptoms of children with relative nocturnal polyuria were diurnal frequency, precipitancy of micturition, and excessive thirst. On the other hand, infrequent diurnal micturition was also not uncommon.

Of these 69 children, 37 had diurnal frequency and 27 of these also had precipitancy of micturition. Excessive thirst—i.e., drinking at least once between each two meals in all weathers—was found in 34 children, and of these 20 had diurnal frequency.

In 31 children the bladder held less than the normal amount of urine—a condition attributed by Braithwaite (1950, 1951) to an achalasia of the detrusor muscle of the bladder. Of these 19 had diurnal frequency, while 6 had only precipitancy of micturition.

The parents of all the children with relative nocturnal polyuria and of a consecutive series of non-enuretic outpatients were questioned about the depth of sleep of the child. More of the enuretics than of the continent children were regarded as being deep sleepers, but 12% of the enuretics were described as light sleepers. Deep sleep, therefore, is by no means an essential accompaniment of enuresis with relative nocturnal polyuria. The connection is not so obvious as that noted by Ström-Olsen (1950) in adults.

No association was found between relative nocturnal polyuria and intelligence. Some sufferers were dull and backward, but several had won scholarships.

FAMILY HISTORY IN RELATIVE NOCTURNAL POLYURIA

Of the 69 children with relative nocturnal polyuria 47 had a family history of enuresis. In all, 67 relatives were affected, of whom 38 were near relatives (siblings or parents) and 29 were distant relatives (uncles, aunts, cousins, or grand-relatives). Of these affected persons 10 were still enuretic in adult life, and 5 were still enuretic as children. All the others had recovered, 5 after passing the age of sixteen, and the remainder at ages evenly distributed between four and sixteen years. Spontaneous recovery from wetting is therefore by no means invariable.

In addition, 12 parents of patients were found who had never been bed-wetters but had, from infancy, always risen at least once a night (in some cases two, three, or more times a night) to void urine. In 4 parents who had been bed-wetters in childhood this symptom had been superseded by the symptom of waking in the night to pass water, when the wetting spontaneously ceased. This symptom might, I suggest, be called excessive nocturnal micturition.

Inquiries about the family history of 20 consecutive continent outpatients revealed only 1 known enuretic relative, and his wetting was only occasional. 7 children with psychogenic enuresis, in whom the diurnal excretory rhythm and the ability to hold urine were both normal, had no family history of enuresis or of excessive nocturnal micturition. The frequency with which enuretic children have a family history of enuresis has been mentioned by many writers (e.g., Batty 1948). From the present series it seems that such a family history is especially characteristic of those children in whom relative nocturnal polyuria is the cause of the enuresis.

Excessive nocturnal micturition also occurs among the relatives of children with relative nocturnal polyuria. It may take the place of enuresis as a symptom if the patient is woken by a full bladder. It also represents one of the ways of spontaneous recovery from nocturnal enuresis, sleep becoming less deep as the patient grows older.

The relation of excessive nocturnal micturition to nocturnal enuresis is illustrated by a pair of female twins aged eight years. These girls were so similar in appearance that only close friends could distinguish between them. Both had relative nocturnal polyuria. One twin was a severe nocturnal enuretic, whereas the other woke three times each night to pass water and was quite dry.

SUMMARY AND CONCLUSIONS

Many children with nocturnal enuresis have an abnormal diurnal excretory rhythm, excreting during the night an unduly high proportion of their total urine. It is suggested that this condition be known as relative nocturnal polyuria. It is sometimes associated with diurnal frequency and with precipitancy of micturition. These symptoms may be due either to polyuria from excessive drinking or to a reduced functional capacity of the bladder.

Relative nocturnal polyuria is often familial, occasionally presenting itself in other members of the family as excessive nocturnal micturition. This latter condition may take the place of nocturnal enuresis, when the stimulus of a full bladder becomes sufficient to wake the patient.

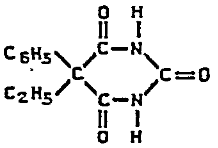
MILONTIN: A NEW DRUG IN THE TREATMENT OF PETIT MAL

J. G. MILLICHAP

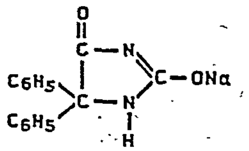
M.D. Lond., M.R.C.P., D.C.H.

SENIOR REGISTRAR, CHILDREN'S DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL, LONDON

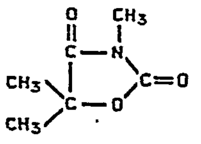
THE relation of 'Milontin' (N-methyl-a-phenyl-succinimide) to other anticonvulsants is shown below:



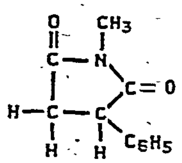
BARBITURATES (*phenobarbitone*)



HYDANTOINS (*phenytoin sodium*)



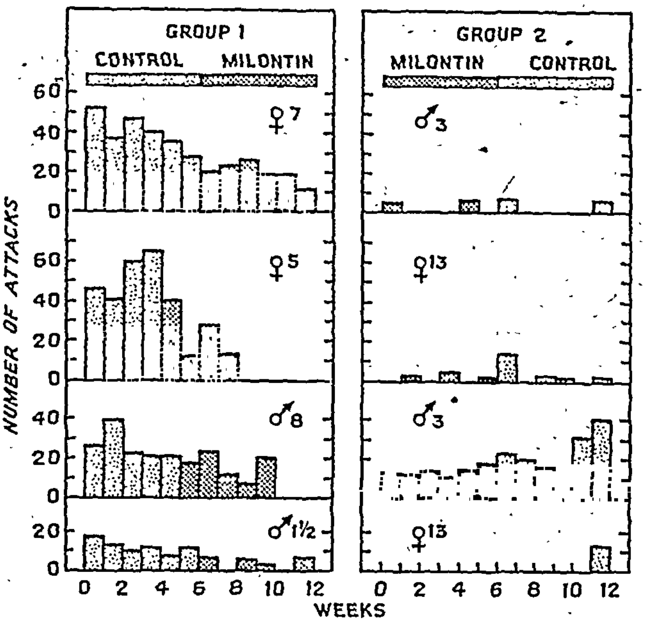
OXAZOLIDINEDIONES (*troxidone or 'Tridione'*)



SUCCINIMIDES (*'Milontin'*)

It was selected for trial in petit mal because of its ability to prevent leptazol convulsions in laboratory animals in non-depressive dosage (Miller and Long 1951). Administered by mouth to mice and dogs it proved relatively non-toxic, and biochemical, hæmatological, and urinary findings remained normal.

Of 20 unselected cases in the present study, which included 17 children, 10 were of pure petit mal (pyknoepilepsy), showing a transient lapse of consciousness, in some cases associated with bilateral rhythmical jerking



Effect of milontin, compared with control capsule, on number of petit-mal seizures.

or twitching of the eyelids but rarely of the head and arms. 5 patients exhibited the akinetic form of petit mal, which includes the salaam spasm of infants and consists of a sudden loss of postural control, with nodding of the head or a fall. This was in some instances accompanied by pykno-epilepsy. In the remaining 5 patients grand mal was combined with one or both of these types of petit mal. One adult with psychomotor and major epilepsy was included in the trial.

Abnormal electro-encephalograms were obtained in 16 patients, of whom 12 gave records pathognomonic, and 3 suggestive, of epilepsy, the classical spike-and-wave complex of petit mal occurring in 6. Since the value of electro-encephalography in diagnosis is limited, cases lacking this confirmation but fulfilling the clinical criteria defined above were not excluded from the trial.

Phenobarbitone had been given previously to 18 patients, of whom 9 also received troxidone and 4 amphetamine. Apart from 1 patient in whom a 75% reduction of attacks was effected after nine months' therapy with troxidone, these drugs had been ineffective or had produced only temporary improvement.

CONTROLLED EXPERIMENT

According to a key retained by the statistician, one of four groups of capsules (A, B, C, and D) was prescribed, of which two contained milontin and two a lactose control. In most cases after six weeks, the alternative capsule (A1, B1, C1, or D1) was substituted and given for an equal period. The parent was provided with a form on which to record the number of seizures each day, and the patient was seen at fortnightly intervals, when the urine and the blood were examined.

TABLE I—EFFECT OF MILONTIN COMPARED WITH CONTROL CAPSULE ON NUMBER OF PETIT-MAL ATTACKS

—	Control		Milontin		Change (%)	Average change (%)
	No. of attacks		No. of attacks			
	Weekly range	Weekly average	Weekly range	Weekly average		
Group 1	27–51(6) 46–64(4) 21–38(5) 7–17(6)	39 52 26 11·8	10–21(6) 12–39(4) 6–23(5) 0–6 (6)	17·0 23·0 15·0 3·8	56 56 42 68	56
Group 2	0–7 (6) 0–13(6) 5–38(6) 0–12(2)	2·17 2·83 21·5 6	0–6 (6) 0–4 (6) 9–17(6) 0 (10)	1·67 1·33 12·70 0	23 53 41 100	54

Length of course in weeks is indicated in parentheses. Patients in group 1 received control capsules first and those in group 2 milontin first.

In the patients who received milontin after a control period the average reduction in the number of petit-mal seizures was 56% (table I); in the patients in whom milontin preceded the control the average increase in the number of attacks was 54%. The efficacy of milontin in the treatment of petit mal is therefore established.

Daily records of the number of attacks were charted for all subsequent patients, and to some of them control capsules were given for the first two or three weeks to obtain for comparison the premedication frequency of attacks. In the 5 patients with both major and minor epilepsy phenobarbitone, alone or with phenytoin sodium ('Epanutin'), was also prescribed. Major attacks were not exacerbated by the introduction of milontin.

RESULTS

The results of treatment were assessed by comparing the average weekly number of seizures during the last five weeks of the milontin course with that of the control or premedication period.

Table II shows that in 5 patients (26%) of the 19 in whom the effect of milontin could be assessed, the attacks were entirely controlled for at least five weeks, the average seizure-free period for the group being nine weeks.

There was a reduction of 80% or more in the number of attacks in 7 patients (37%), and in 4 (21%) the average reduction was 42%. One patient was unaffected, and 2, after temporary improvement, were worse. The effectiveness of milontin was related neither to the type of petit mal nor to the age of the patient. In all the responsive cases the duration and severity of the attacks were much reduced, and in many cases both mental and physical activity was enhanced. These effects were most noticeable in a girl aged 11 who, while taking troxidone, had been introverted and depressed.

TABLE II—EFFECT OF MILONTIN IN 19 UNSELECTED CASES OF PETIT MAL

Petit mal	No. of cases	Average reduction (%)
Entirely controlled	5 (26%)	100
80 % or more reduction	7 (37%)	84
Partial control	4 (21%)	42
Unchanged	1 (5%)	—
Worse	2 (11%)	—

In 1 patient with psychomotor epilepsy, attacks were reduced to 16% of their former number, and their duration was curtailed.

The length of treatment in this preliminary trial ranged from six to twenty-four weeks, with an average of twelve.

TOXIC SIGNS

Of the 21 patients 13 exhibited toxic effects in the following order of frequency (the numbers of cases are indicated in parentheses): abnormal urinary findings (10); drowsiness (5); nausea (4); dream-like state (3); dizziness (2); pyrexia with macular erythematous rash (2); erythema multiforme (1); and vomiting (1).

Minor Side-effects

Nausea, vomiting, pyrexia, and rash occurred with small doses of milontin; but these effects, seen only at the start of medication, were transient and apparently due to idiosyncrasy.

In 1 patient taking milontin 0·9 g. daily erythema multiforme developed within twenty-four hours of

TABLE III—ABNORMAL URINARY CONSTITUENTS AND TOXIC DOSE COMPARED WITH MOST EFFECTIVE DOSE

Case no.	Age (yr.)	Sex	Protein-uria	Micro-scopic hæma-turia	Granu-lar casts	Toxic daily dose (g.)	Most effective daily dose (g.)
1	11	F	+	++	+	2·7	2·7
2	10	F	—	—	+	2·7	1·8
3	8	M	—	++	+	2·7	2·7
4	7	F	+	+++	+	4·8	4·8
5	5	M	—	+	—	2·7	1·5
6	5	F	—	+	—	0·9	0·9
7	4	M	—	—	+	1·8	1·2
8	4	F	—	+	—	0·9	0·9
9	3	F	—	+	—	0·9	0·9
10	2½	F	—	+	—	0·9	0·9

beginning a second course of milontin and necessitated its withdrawal.

Drowsiness, related to the size of the dose and relieved by its reduction, developed only in children. It was apparent in 2 patients, aged eight and eleven years, with a daily dose of 3·6 and 4·8 g. and in 2, aged five years, with 1·8 and 2·4 g. The addition of amphetamine in 1 case neither relieved the drowsiness nor affected the number of seizures. In another, after temporary reduction, the dose of milontin was raised at a slower rate without recurrence of the sign.

Effect on Kidneys and Urine

Evidence of glomerulo-tubular damage, discovered in 10 of 17 children treated, was transient in 7 despite continued medication. In 3 it persisted, and in 1 of these, a child aged seven years taking 4·8 g. daily, its degree necessitated the discontinuance of milontin. For five days her seizures had been completely controlled, and they did not recur when milontin was withdrawn. A week later the urine contained fewer red cells and casts, and subsequent specimens were normal.

As shown in table III, in 3 patients the toxic dose was greater than that producing the best effect, but in 7 these doses were equal. The development of this side-effect was not related to the duration of the treatment.

Increased frequency of micturition occurred in 3 patients, with enuresis in 1.

Against these unfavourable reports in children the following two case-records illustrate a relative lack of toxicity in older patients.

A boy, aged 15, while taking control lactose capsules, developed acute nephritis subsequent to streptococcal tonsillitis. In error milontin was administered during this illness with no deterioration in the urinary findings.

In an attack of automatism a man, aged 39, with psychomotor and major epilepsy, took in a single dose 20 grammes of milontin and 70 grains of phenobarbitone. He was admitted to the *Miller General Hospital*, where, after five days' coma, he recovered. His urine on the third day of coma contained protein 35 mg. per 100 ml., numerous granular casts, and a trace of milontin, but two days later, on his recovering consciousness, no abnormal constituents were found. A blood-count on the fourth day of the illness showed Hb 105%; red cells 5,000,000 per c.mm.; white cells 11,200 per c.mm. (polymorphs 86%, lymphocytes 10%, monocytes 2%, eosinophils 1%); and platelets 200,000 per c.mm. Signs apart from those common to phenobarbitone poisoning were not observed. Milontin being a succinimide derivative, it is worthy of note that sodium succinate has been proposed as an antidote in barbiturate poisoning.

Effect on Blood

Normal cell-counts were obtained in all the patients; but in 1, showing toxic effects with a daily dose of 4·8 g. of milontin, the white cells, which on five occasions had numbered about 9000 per c.mm., fell to 4000 per c.mm., of which 1500 per c.mm. were neutrophils, when hæmaturia and drowsiness were severe. This depression, though not amounting to definite leucopenia, shows the need for caution and repeated blood examinations.

DOSAGE

Milontin was supplied in capsules each containing 0·3 g. To mask the bitter taste, for small children, a suspension of the drug in mucilage was flavoured with syrup of orange.

In all the present cases the initial dosage of 0·3 g. three times a day was increased at intervals of two weeks to 0·6 g., 0·9 g., and 1·2 g. three or four times a day until the greatest effect was secured or toxicity resulted. On this routine, when the most effective dose was exceeded, in some cases the more serious side-effects developed, and it is now considered desirable, provided some improvement is evident, to limit the dose for much longer periods to that suggested in table IV, which shows the average optimum daily dosage and its relation to age.

EXCRETION OF MILONTIN

In part, at least, milontin is excreted in the urine as a glycuronide.

The urine of patients receiving milontin contained a reducing substance on which tests for sugar were negative. On adding it to a solution of benzidine in glacial acetic acid, a pale orange colour resulted which was not obtained with normal urine (Mr. H. F. Weston).

TABLE IV—MOST EFFECTIVE DAILY DOSE ACCORDING TO AGE

Age-group (yr.)	No. of patients	Range of optimal daily dose (g.)	Average optimal daily dose (g.)
1–3	5	0·9–1·2	0·9
3–6	6	0·9–1·8	1·5
6–12	6	0·9–2·7	1·8
Adults	3	1·8–2·7	2·1

Paper chromatography of the urine of 2 patients showed more glycuronide than normal, and on hydrolysis glucuronic acid was released; glucose, in small amount, was also found.

Assessed by its clinical effect in patients with numerous seizures the action of milontin begins within half an hour and lasts about four hours. A cumulative effect was not observed, and on withdrawal, in some cases, there was an exacerbation of seizures.

DISCUSSION

In the initial clinical trial (Zimmerman 1951), based on a study of 50 selected patients with petit mal, milontin equalled or surpassed troxidone in therapeutic efficacy and had the advantage of being relatively non-toxic. Renal damage was not observed, and minor toxic signs appeared in only 11 patients (22%), whose ages were not stated.

The present trial, though corroborating the effectiveness of milontin, was accompanied by a much higher rate of toxicity, and signs of glomerulo-tubular damage, hitherto unreported, were discovered in 10 patients (48%). The large doses used in this series, which consisted mainly of children, could in some cases explain this increased incidence of toxic signs, and a reduction might be effected by using the scheme of smaller dosage suggested. Though the seriousness of renal damage cannot be minimised, in most cases this was transitory, and sequelæ developed in none.

In recommending milontin for further trial the conservatism which stems from caution must be tempered by the urgent need for new and improved therapeutic agents in petit mal.

SUMMARY

The efficacy of milontin in the treatment of petit mal has been established by a controlled experiment. Complete control was obtained in 26% of patients, and attacks were reduced by 80% or more in 37% of patients.

In all the responsive cases the duration and severity of seizures were diminished.

Relief was secured in a patient with psychomotor epilepsy.

In 13 of 21 patients toxic effects were encountered, and signs of glomerulo-tubular damage occurred in 10. The most effective dosage in the present series was related to age, and the more serious toxic effects resulted when this dosage was exceeded.

Further trial is recommended; but, particularly in children, there is need for regular and frequent examination of the urine and the blood.

I am indebted to Dr. Charles F. Harris for his encouragement and permission to carry out this trial in the children's epilepsy clinic. My thanks are also due to Dr. A. White Franklin and Dr. J. Aldren Turner for allowing me to treat their cases; to Mr. M. P. Curwen for statistical advice; to my colleagues in the pathology department, the pharmacists, and lady almoner for their coöperation; to Dr. L. I. Woolf, of the Hospital for Sick Children, for chromatographic investigations; and Dr. Robert Hodgkinson, director of the department of clinical investigation, Parke, Davis & Co., London, for help in the preparation of this paper. Milontin was developed in the research laboratories of Parke, Davis & Co., from whom supplies of the drug were obtained.

GASTROJEJUNOCOLIC FISTULA FOLLOWING GASTROJEJUNOSTOMY FOR INFANTILE PYLORIC STENOSIS

RODNEY MAINGOT
F.R.C.S.

SURGEON TO THE ROYAL FREE HOSPITAL, LONDON

A BOY with infantile pyloric stenosis was treated by posterior gastrojejunostomy at the age of 6 weeks. Thirty-seven years later partial gastrectomy was done for a gastrojejunocolic fistula. Examination of the resected specimen showed that the pyloric tumour had persisted.

CASE-RECORD

A married man, aged 37, was referred to me as a case of gastrojejunocolic fistula. At the age of 6 weeks he had been admitted to a hospital for sick children in Glasgow with intractable vomiting, and diagnosed as having infantile hypertrophic pyloric stenosis. After a short course of treatment he had been operated on in September, 1915, a posterior gastrojejunostomy being done under general anæsthesia. He had had a stormy convalescence and been discharged from hospital about two months after the operation. Since childhood he had always complained of digestive troubles, and he could not ingest large meals, whatever their content. From January, 1936, to November, 1951, he had been treated on many occasions for chronic duodenal ulcer. An analysis of his symptoms during this period, however, would have supported a diagnosis of gastrojejunal ulceration, because in addition to recurrent attacks of acute indigestion, to hunger pains relieved by food, alkaline powders, and vomiting, and to bouts of melæna, there were times when he experienced severe pain localised to the left of the umbilicus and backache situated "to the left of the middle of the spine." Barium-meal radiography from time to time in different clinics confirmed the diagnosis of chronic duodenal ulcer, there being a persistent deformity of the cap. The stoma appeared adequate and to be working in a satisfactory manner. In November, 1951, he had a recurrence of tarry stools, with attacks of vomiting and diarrhœa. The vomitus was "like porridge and evil-smelling, and belching of malodorous gases was uncontrollable." He lost weight rapidly owing to nausea, anorexia, and frequent attacks of vomiting and diarrhœa. Barium-meal radiography established the presence of a gastrojejunocolic fistula. He was admitted to a London hospital on Feb. 15, 1952, for further investigation and preoperative treatment.

On examination the patient was thin, emaciated, and anæmic. His blood-pressure was within normal limits, and there was severe secondary anæmia of the hypochromic microcytic type. His abdomen was scaphoid, with an area of rigidity and tenderness localised to the left of the umbilicus.

Preoperative preparation included a light non-residue diet rich in protein; colonic and gastric lavage with physiological saline solution, blood-transfusions, intramuscular injections of vitamins B and C, adequate dosage of penicillin and streptomycin, phenobarbitone gr. $^1/_2$ thrice daily, 'Soneryl' gr. 3 at night, and 'Sulphathalidine' 2 g. eight-hourly for five days.

Operation.—On Feb. 23, under general anæsthesia, the epigastric scar was excised and the abdomen was explored through a lengthy left paramedian incision. After adhesions had been freed and the diagnosis of gastrojejunocolic fistula had been confirmed, the abdominal viscera were explored. The pylorus was found to be enlarged, bulbous, and firm, with the antral mucosa thrown into long folds. The gall-bladder, liver, pancreas, spleen, and small intestine were normal. A portion of the transverse colon was drawn into, and welded in, a mass of scar tissue to the gastro-enteric stoma. A posterior gastrojejunostomy had been done with a short afferent limb; the stoma was contracted and felt like a small fibrotic ring; an extensive gastrojejunal ulcer, adherent to the pancreas, involved a portion of the stoma and the adjacent part of the efferent jejunal limb; the fistulous tract into the colon readily admitted the index finger; and the stomach wall was hypertrophied, dilated, and œdematous. The colon was separated from its broad fistulous attachment to the water-logged efferent limb of jejunum; and after the sclerotic margins of the opening in the large bowel had been trimmed away, the circular defect in the antimesenteric border of the gut was closed transversely with a Connell loop-on-the-mucosa suture of no. 0 medium chromic catgut and reinforced with a series of closely applied interrupted sutures of fine black silk. Through the gaping hole in the jejunum the base or crater of the gastrojejunal ulcer, which was deeply excavating the pancreas, could be seen. The jejunum was cut free from its line of union with the stomach, and the resulting opening in the small gut was closed after the Finney method of gastro-duodenostomy for duodenal ulcer. The stomach was next mobilised and, after the right gastro-epiploic artery had been isolated, ligated, and divided, and the middle colic blood-vessels had been identified and protected, the stomach was cut adrift from its anchorage to the pancreas. At this stage the liberated first part of the duodenum was transected between clamps, and the distal end was securely invaginated. The base and edges of the gastrojejunal ulcer, which formed a large crater in the pancreas, were destroyed with a diathermy button, after which the left gastric artery was secured and two vasa brevia were underrun with strong silk sutures mounted on aneurysm needles, tied off in continuity, and divided close to the greater curvature.

The stomach was now ready for resection and anastomosis. About three-quarters of the stomach was resected, and the operation was completed by the antecolic Polya-Hofmeister technique. The afferent limb of the jejunum was brought over the transverse colon from right to left, buttressed to the "new" lesser curve, and anastomosed to the small gastric pouch. The afferent limb of the jejunum lying superior to the colon was anchored to the capsule of the pancreas with two sutures of fine silk to prevent rotation, kinking, or volvulus. A drainage tube was passed down to the burnt area of the ulcer crater; the wound was closed with interrupted floss-silk sutures, and the skin margins were approximated with 'Mersilk.'

Immediate postoperative treatment followed conventional lines: *intermittent gastric suction* through a Ryle tube, 2 oz. of water by mouth hourly, blood-transfusion, morphine for pain, intramuscular injections of sodium phenobarbitone for restlessness, the *administration* of vitamins B and C, intramuscular injections of large doses of penicillin, and deep-breathing exercises. The patient made a good recovery and was ordered a generous *non-residue* diet on the seventh day after operation. The drainage tube was removed on the third day, and stitches on the sixth; and the patient was discharged from hospital on the twentieth day after operation.

Pathology.—Examination of the resected specimen showed no evidence of duodenal ulcer; *the* pyloric tumour had persisted; the pylorus was enlarged, barrel-shaped, and fibrotic; and the antral mucosa was thickened and thrown into prominent longitudinal folds. Sections of the margins of the gastrojejunal ulcer showed no signs of malignancy.

Follow-up.—After a short holiday in Scotland the patient returned to Trinidad, and on May 20 I received a letter from him in which he stated: "You will be glad to hear that I am back at work as an engineer in an oilfield and that I am quite well. I have gained 15 lb. in weight, and my appetite is good. I have enjoyed all my meals and am ready for more, and I have never felt so fit, eager for work, or so pleased with life as I am at the present time."

DISCUSSION

Gastrojejunal ulceration is a dangerous and common sequel to gastrojejunostomy, and the number of cases in which this complication occurs multiplies steadily as such patients are observed over increasing periods after the operation. The commonest cause of gastrojejunal ulcer is gastrojejunostomy for duodenal ulcer, the incidence being about 20–30%. The majority of marginal ulcers declare themselves within two years of operation. The occurrence-rate of anastomotic ulcer following operations for duodenal ulcer depends on the type of operation. Thus it is common after anterior or posterior gastrojejunostomy, partial gastrectomy after the Roux-Y procedure, antrectomy, Devine's gastric exclusion, gastrectomy combined with entero-anastomosis, and Finsterer's method of antral exclusion combined with gastric resection. It is becoming apparent that the Billroth-I operation for chronic duodenal ulcer is more productive of stomal ulceration than is a well-conducted Polya type of repair, and that vagotomy combined with a short-circuit operation will be followed in at least 5% of cases by marginal ulcers within three years. Gastrojejunal ulceration is rare (about 1 case in 400) after the Billroth-I types of repair and after the Polya operations for *gastric* ulcer. The operation of choice for chronic duodenal ulcer is gastroduodenal resection in which at least 70–80% of the stomach is resected and the operation is completed by the antecolic Polya-Hofmeister technique. If this extensive resection is impracticable, vagotomy combined with gastrojejunostomy should be done. The patient had a gastrojejunostomy done for infantile pyloric stenosis some three years after the publication of Ramstedt's articles in 1912. Before the advent of Ramstedt's operation of pyloromyotomy, numerous procedures were advocated for the cure of this anomaly, including pyloroplasty by the Heinke-Mickulicz method, Fredet's operation, duodenopylorectomy, Loreta's operation, and gastrojejunostomy. Loreta's operation of divulsion of the constricting pyloric tumour was a failure except in the expert hands of Burghard, and the other operations mentioned had a damning mortality of 50–80%.

When was Ramstedt's operation generally accepted as the procedure of choice for infantile pyloric stenosis? This question can only be answered accurately by studying the operation notes of such cases in various hospitals for infants and by recording the surgical methods selected for the cure of this disease during the anxious years of the 1914–18 war. Few patients with infantile pyloric stenosis were subjected to gastrojejunostomy after September, 1915, and the number who survived this operation were even fewer. Armitage and Rhind (1951) reported a case of gastrojejunal ulcer following gastrojejunostomy for infantile pyloric stenosis for which partial gastrectomy was done. Examination of the excised specimen, as in the present case, showed that the pyloric tumour had persisted into adult life.

Some 10–15% of patients with gastrojejunal ulcer develop gastrojejunocolic fistula; but this sinister complication following, as in the present case, an operation for infantile pyloric stenosis which has been obsolete for over thirty years must be extremely rare.

COMPLEMENTARY ACTIVITY OF THE BLOOD IN ACUTE NEPHRITIS*

WITH SPECIAL REFERENCE TO PROGNOSIS

C. E. KELLETT
M.D. Camb., F.R.C.P.
PHYSICIAN, NEWCASTLE GENERAL HOSPITAL

SIXTEEN years ago, in a paper published in this journal, attention was called to the fall that takes place in the complementary activity of the blood in acute glomerulonephritis (Kellett 1936a). Such a fall suggested that an antibody-antigen reaction had taken place, and its extent was such that it seemed improbable that such a reaction should have been localised to the kidneys. That same year evidence was published (Kellett 1936b) which suggested that serum disease in man was a manifestation of reversed active anaphylaxis, and it seemed that acute nephritis might prove to be a particular example of this process. This hypothesis was in accord with Masugi's (1934) experimental work in which he produced acute glomerulonephritis in rabbits by injecting specific anti-organ sera, and with the analogy drawn many years before by von Pirquet and Schick (1905) between the specific complications which may follow scarlet fever and those which may follow the administration of serum.

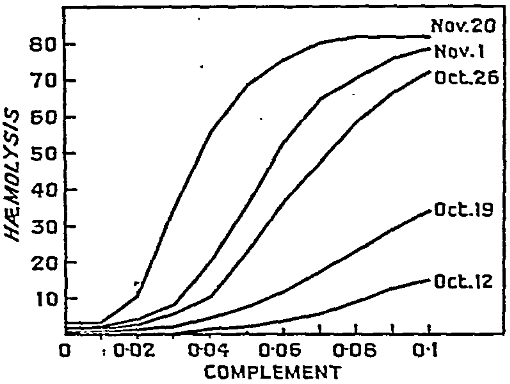

Fig. 1 (case 1)—Rise in complementary activity of blood in six weeks following admission. Activity is measured as the percentage hæmolysis produced by increasing amounts (expressed in ml.) of the patient's serum.

This fall in complementary activity had previously been noted by Gunn (1914–15) and by Weil and Bucholz (1932) and is mentioned in passing by Browning (1912–13). According to Masugi (1939) it was confirmed in Japan by

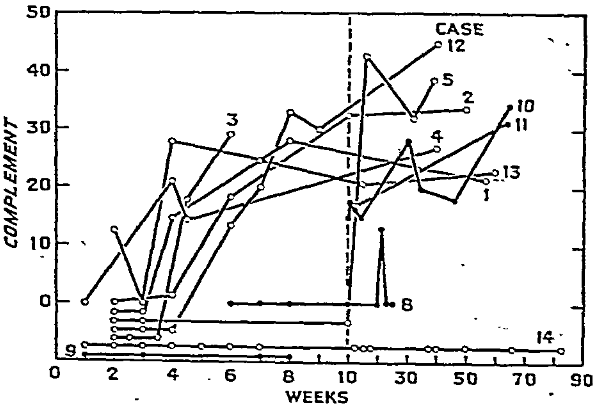

Fig. 2—Changes in complementary activity (expressed in units per ml.), in 12 cases of acute nephritis, from the outset of illness.

---

* Based on a communication to the Society of Pathology and Bacteriology, June, 1951.

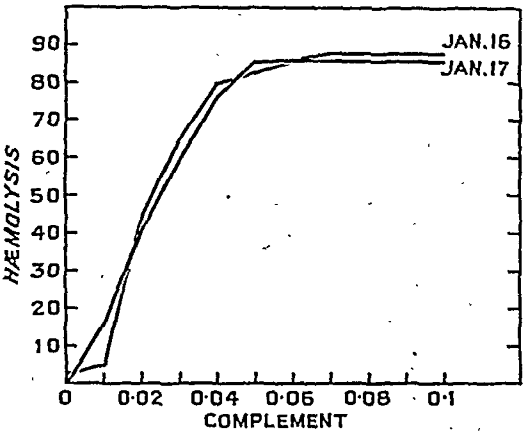

Fig. 3 (case 6)—Eclampsia. Complementary activity unaffected by convulsions. Activity expressed as in fig. 1.

Ogawa and Sato and by Hayashi. In this country it was confirmed by Thomson et al. (1939), who observed that a similar fall did not occur in acute eclampsia. Thomson and I published pathological evidence supporting the belief that this fall takes place in acute glomerulonephritis and not in any other form of Bright's disease (Kellett and Thomson 1939). Recently Reader (1948) has again investigated and reviewed these changes, which have been the subject of a further paper (Lange et al. 1951), published since much of my present article was written.

This paper is concerned not so much with the diagnostic as with the prognostic significance of this change and of the rate of return to normal, and advantage has been taken of the work summarised by Heidelberger and Mayer (1948), the method of estimation adopted being based upon their recommendations. In each estimation use is made of differing dilutions of the serum to be tested, so that the result is expressed as a curve from which one can deduce the least amount of serum—here called a unit—required to bring about 50% hæmolysis in the system.

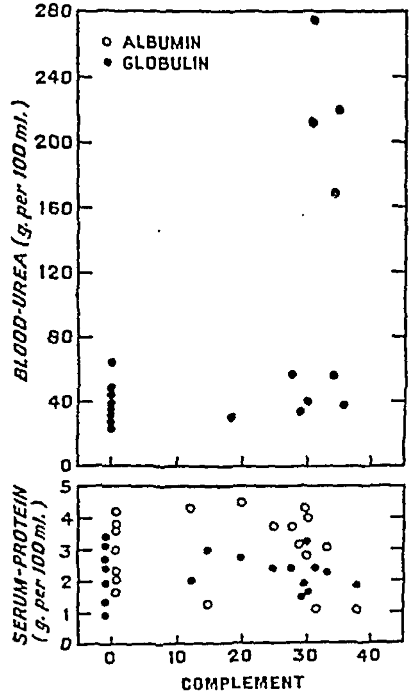

Fig. 4—Readings in cases of acute nephritis showing lack of relation between complementary activity, on the one hand and serum-proteins or blood-urea on the other.

CASES AND COMMENTS

In the following case the findings were not unlike those reported by me previously (Kellett 1936a).

Case 1.—A man, aged 29, was admitted on Oct. 10, 1950, with frontal headache, and swelling of the feet and face for a week. On the day before admission he had vomited three times and on day of admission he had four fits. Blood-pressure (B.P.) 165/100 mm. Hg. The urine contained a large amount of albumin, together with numerous hyaline and granular casts, and the blood-urea was 58 mg. per 100 ml. He was discharged on Oct. 31, and has since remained perfectly fit. When he was last seen a year later his B.P. and urine were normal. The rise in the complementary activity of his blood in the six weeks following admission is shown in fig. 1.

This type of response, in which there is a fairly rapid return of the complementary activity to normal, is that usually encountered in cases of acute nephritis in which apparent recovery takes place. Fig. 2 includes readings recorded in this and four other typical cases of acute nephritis in a boy of 5 (case 2), a man of 43 (case 3), a boy of 8 (case 4), and a boy of $4^{1}/_{2}$ (case 5). In cases 2–5 the onset was less dramatic than in case 1; but in our experience the apparent severity of the onset bears no relation to the degree of the fall in complementary activity or to the ultimate prognosis. The complementary activity remains remarkably unaffected even by repeated convulsions, such as are met with in acute eclampsia:

Case 6.—A woman, aged 24, nearly at term, was admitted on Jan. 15, 1952, to the Richard Murray Hospital under the care of Mr. W. Hunter, suffering from acute eclampsia. She had had five fits before admission and shortly afterwards she had a further two. When seen she was cyanosed, her features were thickened and in many ways suggestive of pituitary upset, and she was drowsy and roused with difficulty. Her urine contained large quantities of albumin. Her B.P. was 180/120. She was sedated with morphine, chloral, and bromide. She had a further six major fits during the night, but was then delivered of a normal healthy child, and made an uninterrupted recovery. A week after admission her B.P. was 135/90. Fig. 3 shows the complementary activity of two samples of blood, the first taken after the first seven eclamptic fits and the second after she had had a further six fits and been delivered of her child.

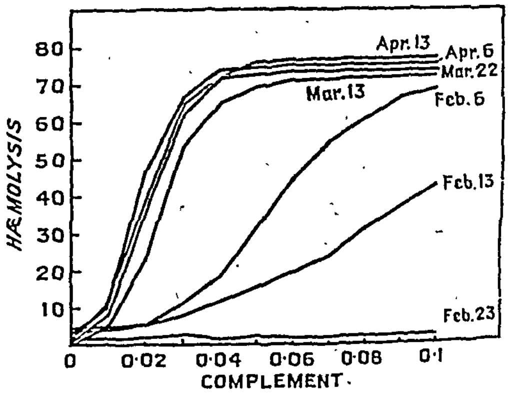

Fig. 5 (case 7)—Complementary activity returns to normal with improvement in renal condition, despite congestive heart-failure which proved fatal. Activity expressed as in fig. 1.

The mode of onset seems to depend on the particular tissues affected and on the temperament of the patient rather than on the degree of renal damage sustained. This is also true of the initial fall in complementary activity, which is not related directly to renal damage. In the terminal stage of nephritis and pyelonephritis, when the renal damage may be extreme, the complement remains at normal level.

This lack of any clear-cut relation between the level of the complementary activity of the blood-serum on the one hand, and the serum-proteins or blood-urea on the other, is clearly shown in fig. 4, which summarises my experience in different cases.

On the other hand, the rate of return of the complementary activity of the blood has often seemed to be closely related to the ultimate prognosis of the renal condition—though not necessarily to the disease process as a whole.

Case 7.—A man, aged 21, was already very ill when he came into hospital on Feb. 1, 1951, and recovery seemed unlikely. He had had rheumatic fever at the age of 6 and since then had had frequent colds and sore throats, but had remained fairly fit until an attack of influenza two days before Christmas. He then became pale and breathless, with swelling of feet and ankles. On admission his temperature was about 101°F, his pulse-rate 112, and his B.P. 140/70. There was loud apical systolic murmur and *Streptococcus viridans* was isolated from his blood. His urine contained a considerable amount of albumin and his blood-urea was 84 mg. per 100 ml. He was given a long course of penicillin, having in all nearly 160,000,000 units, and at first his general condition improved and he became afebrile. His blood-urea dropped to 30 mg., but his pulse-rate became more rapid and he began to fibrillate and developed signs of congestive failure. These were brought temporarily under control with digitalis, mercurial diuretics, and a low-salt diet; but he gradually ceased to respond to treatment and he died of congestive heart-failure three months after his admission, a final blood-urea having risen to 100 mg. Despite this his complementary activity, after an initial depression, had steadily returned to normal (fig. 5).

In this case the complement returned to normal as the nephritis subsided, despite the ultimate death of the patient from cardiac failure, whereas in case 8, in which the nephritis caused death several months after its onset, the complementary activity of the blood remained impaired.

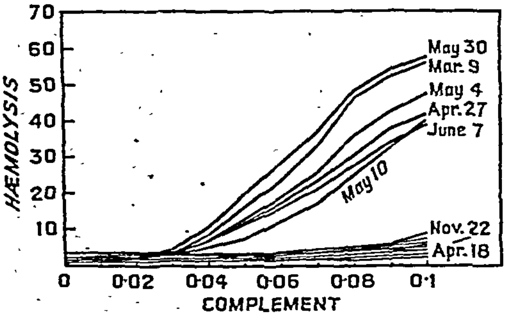

Fig. 6 (case 8)—Complementary activity during seven months of glomerulonephritis ending in death on June 8. Activity expressed as in fig. 1.

Case 8.—A man, aged 39, was admitted on Nov. 21, 1950. He had had a cold three weeks previously. Two weeks later his ankles had become swollen and his face puffy and he was becoming short of breath and had severe headaches. His B.P. was 130/75, and his urine contained much albumin and a few red cells and white cells. He steadily went downhill, being readmitted on Jan. 17, 1951, and remaining in the ward until his death on June 8.

In this case death seemed to have been caused by the progressive impairment of renal function, and the complementary activity of the blood was reduced throughout the illness, though at times it showed a slight improvement (fig. 6). This was in striking contrast with the findings reported in my first paper (Kellett 1936a) (which dealt, however, with only 3 patients with acute nephritis, all of whom recovered) and with the majority of our results during the past few months. Moreover, the following case suggests that these continued low readings were the expression, not so much of the persistence of the initial infection, but of the persistence of certain reactions of the body following infection.

Case 12.—A man, aged 40, was admitted on Feb. 5, 1951, as a case of acute nephritis. He had been quite well until ten days previously, when he developed influenza and a sore throat. Five days later his face had become puffy, also his hands and feet, and this was followed by headaches and vomiting four or five times a day. His urine had become dark and he was passing very little. His B.P. on admission was 155/95. His urine contained large amounts of albumin, and red and white cells, and his blood-urea was 156 mg. per 100 ml.

He seemed to have a classical acute nephritis, but in addition he gave a history of about 20 shivering attacks, lasting a few minutes each, six days before admission. He had cellulitis of the right side of the face together with redness and tenderness behind the left ear, with some local pitting œdema. Accordingly he was given aureomycin and penicillin, having in all 30 g. of aureomycin and approximately 20,000,000 units of penicillin. His temperature dropped at once, and his face returned to normal within a week. But a week after the penicillin was discontinued, his face became swollen again, the temperature rose, and he had repeated shivering attacks. Penicillin was administered over the next seventeen days, once more in large quantities, and he was kept under observation for a further two months. When seen in October, 1951, he seemed perfectly fit and his urine was normal.

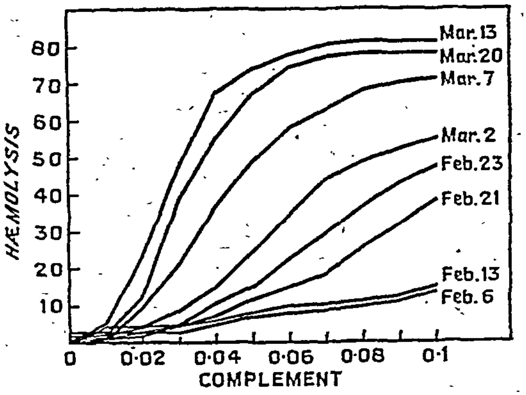

Fig. 7 (case 12)—Complementary activity unaffected by recurrence of cellulitis of face between Feb. 26 and March 2. Activity expressed as in fig. 1.

In this case of acute nephritis a recurrence of the severe and striking initial infection produced neither an exacerbation of the nephritis, nor a change in the rate of return of the complement (fig. 7).

A persistently low level of complementary activity does not, however, invariably imply progressive renal damage.

Case 14.—A woman of 20 was admitted on June 23, 1950. Eight weeks previously she had been delivered of a healthy child and five weeks after this she developed a sore throat. Ten days later her legs, hands, and face had become œdematous. On admission her B.P. was 150/100, and there was pitting œdema of the legs up to the thighs. The urine contained albumin +++ and an excess of leucocytes, red cells, and hyaline and granular casts. The serum-proteins were 3 g. per 100 ml. and the blood-urea was 64 mg. per 100 ml. Her

condition slowly improved until her discharge on Aug. 22: the serum-proteins were 7 g. per 100 ml. and the urine contained albumin +, a few red and white cells and no casts. Since then she has appeared to enjoy excellent health. In January, 1951, the total proteins were 6 g. per 100 ml. and the urine contained albumin and a few white cells. In October, 1951, though she felt well, there was still a trace of albumin in her urine and her B.P. at 142/95 was still a little raised, while the blood complement remained low (fig. 3).

Though in this case recovery has not yet taken place, the renal changes have seemed *relatively slight.*

We seem, nevertheless, to be dealing with a real impairment in the complementary activity of the blood rather than with an active neutralisation by some substance of an anticomplementary nature; for, as is shown in fig. 8, the addition of similar fractions of serum from these cases to those of other cases in which the complementary activity was almost normal or normal, does not bring about any obvious inhibition, the final curve being in each case higher.

In 3 other patients (cases 9, 10, and 11) a delay in the return of the complementary activity to normal did seem to be associated with delay in their recovery though in one (case 10), a child aged 14 who died of subacute nephritis, this had been reached at the time of her death. Again, in case 13, the fall noted in the second estimation and shown in fig. 2 did coincide with the reappearance of red blood-cells in the urine and a rise in blood-pressure lasting two or three days.

Despite the difficulties inherent in case 10, and in the fact that similar falls in the level of complementary activity have been seen in certain other conditions, some of which do not appear to be directly related to nephritis, it is possible that this delay in returning to normal is in some way linked with the persistence of the underlying disease process. If that is so, it would seem as though, in type-II nephritis, in which the complement is normal, this particular process has finished some time before the terminal changes have begun in the kidneys and thus called attention to the condition. This also applies to many cases of type-I nephritis in the terminal stages, which again would appear to have been brought about as a result of the damage sustained by the kidneys, rather than as a result of the persistence of the original disease process. Apparently the initial damage to the kidneys may be so severe, or spread over so long a time, that it causes irreversible changes; and if, as I think probable, these changes are associated with a low complementary activity, this test will be most likely to aid prognosis during the first three months or so after the onset of the condition.

SUMMARY

The fall in the complementary activity of the blood which has been described in acute nephritis has been confirmed. However, a similar fall can occur in certain diseases not directly related to acute nephritis. While a delay in the return of the complementary activity to normal is usually associated with progressive renal deterioration, in one case at least the complement remained low for over a year without any obvious deterioration. It seems probable that reduced complementary activity in the early stages of a nephritis indicates acute glomerulonephritis, and that a considerable delay in the return to normal implies a relatively poor prognosis.

It is a pleasure to have this opportunity of thanking Miss G. Partington, B.SC., my technical assistant, who carried out the complementary estimations; my colleagues, for their ready coöperation; and the Newcastle upon Tyne Regional Hospital Board for the research grant which made this work possible.

Preliminary Communications

EXPERIMENTAL COOLING OF THE BLOOD-STREAM

IN a number of centres research into the physiological effects of cold has been receiving increased attention. This preliminary communication deals with the results obtained during the past two years by a method which I have developed in the Wilkie Surgical Research Laboratory. By this method the animal is cooled by circulating its blood through a refrigerating system outside the body. The physiological response differs fundamentally from that with previous methods, by which cold is applied to the surface of the body.

The apparatus that has proved most suitable is a double-coil glass condenser of 850 sq. cm. cooling-surface, through which arterial blood is diverted to lower its temperature by 10°–20°C before it is returned to the body through a peripheral vein. All surfaces in contact with blood are coated with a baked silicone film. The coolant is ice-water recirculated by a small pump through the double coils of the condenser. In addition a weak heparin-procaine solution in isotonic glucose is given slowly into the arterial cannula during the time that the blood is circulating through the apparatus. When intrathoracic procedures are planned, quinidine sulphate (50 mg. per kg. body-weight, intramuscularly) is given. Artificial respiration is always necessary early in the cooling process.

TABLE I—ANALYSIS OF DEATHS

No. of animals	Cause of death
1	Delayed infarction of bowel due to accidental rise of body-temperature from 25° to 30°C during occlusion of visceral arteries.
1	Acute cardiac dilatation and failure due to too rapid intra-arterial replacement of blood following prolonged exsanguination.
1	Hæmothorax 20 hours postoperatively due to over-heparinisation and extensive dissection of mediastinum.
1	Ventricular fibrillation following extreme cooling (22°C) in absence of procaine and quinidine.

TABLE II—EXPERIMENTS INVOLVING LOCAL ISCHÆMIA, WITH SURVIVAL

Procedure	Duration of test	Effect at normal body-temperature	No. of experiments
Bilateral renal ischæmia	4 hr.	Lethal after 4 hr.	1
Visceral ischæmia (ligation of cœliac, superior and inferior mesenteric arteries, and hepatic artery)	3 hr.	Lethal after 3 hr.	1
Partial cerebral ischæmia (tourniquet)	10 min.	?	1
Complete cerebral ischæmia (ligation of both brachiocephalic arteries)	20 min.	?	2
Myocardial ischæmia (ligation of main descending branch of left coronary artery)	5 min.	Lethal after 2½–5 min.	2

RESULTS

At first some difficulties were encountered in establishing the rate and degree of cooling of the blood which would result in uniform reduction of tissue temperature without undesirable side-effects, but the intense reac-

tionary responses associated with surface cooling (neuromuscular, vascular, and humoral) were not seen; thus the difficulties and dangers of cooling were reduced. The thermal gradients within the body which result from surface cooling have been shown to initiate dangerous cardiac irregularities.[1] Hypothalamic heat-regulating responses including shivering, as well as thyroid and adrenal calorigenic effects, are restricted by the rapidity of the deep cooling when the blood-stream is directly cooled.

In 33 consecutive experiments, unselected mongrel dogs under pentobarbitone anæsthesia, were cooled rapidly (0·5°C per minute) to body-temperatures between 22° and 26°C, and then subjected to various procedures that would have brought about the death of a normal animal. 4 deaths followed, all at least partly attributable to technical faults (table I).

In the remaining 29 animals, 35 separate procedures were carried out at body-temperatures of 24°–26°C. After body-temperature was restored to normal, uncomplicated recovery ensued in all animals without any sign of neurological or other defect (tables II–IV). In one experiment in which cardiac arrest occurred when the body-temperature reached 22°C, regular and effective heart action was maintained by a bipolar electrode passed down the jugular vein into the right auricle. Spontaneous cardiac activity returned with a rise in body-temperature. This suggests a means of producing temporary quiescence of the heart, which is very desirable in certain forms of cardiac surgery.[2]

TABLE III—EXPERIMENTS INVOLVING GENERAL ISCHÆMIA, WITH SURVIVAL

Procedure	Duration of test	Effect at normal body-temperature	No. of experiments
"Lethal" hæmorrhagic shock (B.P. 40 mm. Hg or less)	4–5 hr.	Average survival-time 4 hr.	3
Occlusion of venous return to heart	20 min.	Survival-time $4^1/_2$–18 min.	4
Occlusion of venous return to heart plus occlusion of ascending aorta	Venous 10 min., arterial 5 min.	?	1
Arterial exsanguination	1–$2^1/_2$ hr.	Survival-time 3–4 min.	12
Exsanguination and occlusion of venous return, followed by cardiotomy with exposure of interior of right ventricle and exploration of pulmonary artery	1 hr. (ventricle open for 20 min.)	Immediate death	2

These results do not indicate the maximal resistance of cooled animals to each procedure. The various tests were designed to exceed the degree of injury known or estimated to be lethal to animals at normal body-temperature. It would appear that at this level of cooling functional rather than pathological changes take place, and that under certain forms of stress these changes may be of advantage to the organism. No histological damage has been found in any tissue following cooling and the functional changes are completely reversible.

Bigelow et al.[3] showed that when dogs are subjected to surface cooling an oxygen debt does not develop; during this period oxygen supply is therefore at least adequate to meet oxygen requirements. From my experiments it would appear that not only is this true but that also during cooling reduction in oxygen demand is much greater than reduction in oxygen availability, and a relative oxygen surplus exists at the capillary level. Thus tissues partly or entirely deprived of their blood-supply for periods considerably exceeding the lethal period at normal temperatures can, at these lower temperatures, survive without evidence of transient or permanent injury.

TABLE IV—MISCELLANEOUS EXPERIMENTS, WITH SURVIVAL

Procedure	Duration of test	Effect at normal body-temperature	No. of experiments
Asphyxia (clamping intratracheal catheter)	10 min.	Survival-time 4–6 min.	2
Prolonged cooling at 25°C for 24 hr. using electrophrenic respiration	24 hr.	?	1
Cooling without rewarming	Return of voluntary respiration and normal body-temperature after 24 hr.	—	1
"Lethal" tourniquet shock (bilateral tourniquets on hind-limbs)	5 hr.	Lethal after 5 hr.	1
Artificial control of action of cooled heart by intracardiac stimulation	50 min.	?	1

The effect of cooling in preventing the usual sequence of late events in oligæmic shock (capillary paralysis with increasing vascular capacity) may be due not only to the reduced oxygen demand of the tissue-cells but also to depression of harmful enzyme activity which occurs when the cell is injured by anoxia; for example, it is significant that the limbs did not swell after five hours of tourniquet-ischæmia.

These findings raise the hope that controlled hypotension in surgery may be employed more safely and more intensively in conjunction with cooling of the blood-stream. "Cold" surgery may extend the dry field enjoyed by the orthopædic surgeon to the brain, the heart, and the abdominal viscera, and even in the surgery of the extremities may eliminate the danger of ischæmic damage. There may be special indications for "cold" surgery in operations for congenital heart defects and when surgical emergencies arise in the presence of acute fevers.

SUMMARY

Cooling of the blood-stream appears to be a practicable method for lowering the respiratory activity of the cell without depressing the function of essential tissues below a level compatible with life. At 25°C body-temperature dogs can survive drastic and prolonged reductions in blood volume as well as suspension of blood-flow, both locally and systemically. Cooling brings about what might be termed temporary degradation of the more delicate higher organism to the level of the more resistant lower organism, and in so doing enables it to withstand otherwise lethal ischæmia.

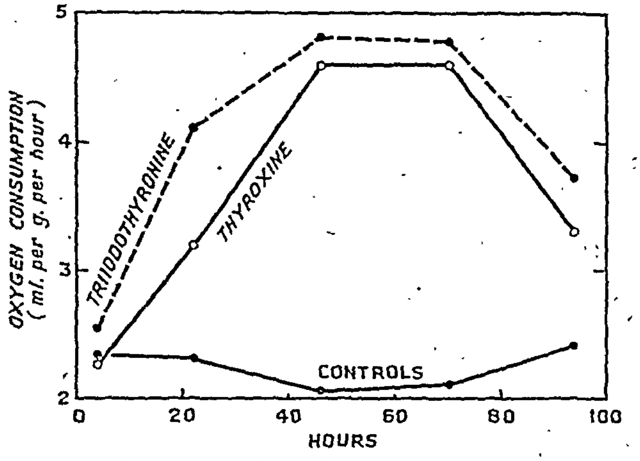
EFFECT OF 3:5:3′-L-TRIIODOTHYRONINE AND CERTAIN ANTI-THYROXINE SUBSTANCES ON THE OXYGEN CONSUMPTION OF MICE

IN view of recent work on the isolation, preparation, and properties of 3:5:3′-L-triiodothyronine (Gross and Pitt-Rivers 1952a and b, Roche et al. 1952), we considered the effect of this substance upon the oxygen consumption of mice to be of interest. Of six groups of 8 mice, two were treated with sodium L-thyroxine (1 mg. per kg. body-weight) by subcutaneous injection, two with an approximately equimolar dose of triiodothyronine (0·84 mg. per kg.), and two were injected with 0·1% W/V Na_2CO_3 to serve as controls. The oxygen consumption of each group was measured by the method of Maclagan and Sheahan (1950). The results are shown in the accompanying figure. It will be observed that triiodothyronine pro-



Effect of triiodothyronine and thyroxine on oxygen consumption of mice.

duced a somewhat greater increase of oxygen consumption than thyroxine. The latent period was about the same as that of thyroxine, whilst the duration of the effect was similar. Statistical analysis showed that the difference between the two groups was highly significant at four and twenty-two hours ($P<0·01$). This general trend obviously continues, although there is more overlap between individual readings at the later times.

Further experiments were performed to determine whether the antithyroxine drug, *n*-butyl 3 : 5-diiodo-4-hydroxybenzoate (B.D.H.B.) (Sheahan, Wilkinson, and Maclagan 1951), and the analogous *n*-butyl 3-iodo-4-hydroxybenzoate (B.I.H.B.), were capable of inhibiting the triiodothyronine. Some typical results appear in the table.

Contrary to expectation, in acute experiments, B.D.H.B. produced a slight but significant *increase* in oxygen consumption, and in chronic experiments both B.D.H.B. and B.I.H.B. produced a similar increase. In the latter experiments this increase was all the more striking because of the considerable depression of metabolism produced by both substances when given alone. These results with triiodothyronine are, of course, entirely different from the marked *decrease* produced by B.D.H.B. in the metabolism of mice treated with thyroxine, which has previously been reported (Sheahan et al. 1951, Maclagan, Wilkinson, and Sprott 1952).

THE EFFECT OF B.D.H.B. AND B.I.H.B. ON THE RESPONSE OF GROUPS OF 16 MICE TO 3:5:3′-L-TRIIODOTHYRONINE

Compound	Mode of administration	Mean oxygen consumption as percentage of controls ±SE	Significance (Student's t test)
Triiodothyronine	0·84 mg./kg. subcutaneously	192 ±5·5	P <0·01
Triiodothyronine + B.D.H.B.	0·84 mg./kg. subcutaneously + 2×200 mg./kg. subcutaneously	224 ±3·3	
Triiodothyronine	0·25 mg./kg. subcutaneously	165 ±2·3	Not significant
Triiodothyronine + B.I.H.B.	0·25 mg./kg. subcutaneously + 2×200 mg./kg. subcutaneously	170 ±4·2	
Triiodothyronine	0·5 µg./g. dry diet for 2 days 0·1 µg./g. dry diet for 6 days	135 ±4·2	P <0·001
Triiodothyronine + B.D.H.B.	As above 0·3% of dry diet	154 ±2·2	
B.D.H.B.	0·3% of dry diet	78 ±3·1	
Triiodothyronine	0·5 µg./g. dry diet for 2 days 0·1 µg./g. dry diet for 6 days	135 ±4·2	P <0·01
Triiodothyronine + B.I.H.B.	As above 0·3% of dry diet	153 ±2·8	
B.I.H.B.	0·3% of dry diet	68 ±2·3	

This result appears to be of interest in relation to the nature of the normal thyroid hormone, at least in the mouse. Since B.D.H.B. and B.I.H.B. profoundly depress the metabolism of normal animals in spite of their inability to antagonise triiodothyronine, the main circulating thyroid secretion seems more likely to be thyroxine than triiodothyronine. Our findings are nevertheless consistent with the suggestion (Gross and Pitt-Rivers 1952b), that thyroxine may require conversion to triiodothyronine in the tissues before becoming physiologically active. In this event these inhibitory compounds might owe their activity to interference with this preliminary deiodination, the inhibitor exercising some form of competition with thyroxine in the enzyme systems concerned. The synergistic effect of the "inhibitor" with triiodothyronine could be explained on a similar basis, if it is assumed that the normal mode of destruction of triiodothyronine involves dehalogenation, which is again restrained by the B.D.H.B.

Our views on the mode of action of anti-thyroxine compounds (Sheahan et al. 1951) require some extension in the light of these experiments. While these substances certainly antagonise the metabolic effects of thyroxine, if the view advanced above is correct this antagonism might be of a somewhat less specific nature than was previously envisaged, the inhibitor merely exercising a restraint on certain deiodinating processes. Experiments designed to test this hypothesis are being carried out.

EXPERIMENTAL

3-Iodo-4-hydroxybenzoic Acid. *p*-Hydroxybenzoic acid (13·8 g.) was iodinated with iodine (25·4 g.) in ammonia solution (100 ml., s.g. 0·88) by the method of Datta and Prosad (1917). When iodination was complete the mixture was adjusted to pH 4 to precipitate a small amount (1·2 g.) of the diiodo acid. After filtration, the filtrate was acidified to pH 2, when the required acid (20·2 g., 77%) separated. After recrystallisation from water it had m.p. 176–178°. Brenans and Prost (1923) report m.p. 173° (mol. wt. by titration: 270. Calc. for $C_7H_5O_3I$: 264).

The *n*-butyl ester was prepared by refluxing a mixture of the acid (5·28 g.), *n*-butanol (50 ml.), benzene (50 ml.), and sulphuric acid (1 g.) for five hours, during which time the water produced in the reaction was removed by means of a McIntyre still-head. The acid was neutralised and the organic solvents removed by steam distillation. On cooling, the required *n-butyl 3-iodo-4-hydroxybenzoate* solidified (5·37 g., 84%). After recrystallisation from 95% methanol it formed colourless needles, m.p. 100–101°. (Found : C, 41·3 ; H, 3·9 ; I, 39·8%. $C_{11}H_{13}O_3I$ requires C, 41·3 ; H, 4·1 ; I, 39·7%).

The work was aided by a grant from the Medical Research Council to one of us (N. F. M.). The 3:5:3′-L-triiodothyronine and L-thyroxine used were kindly provided by Glaxo Laboratories Ltd.

Medical Societies

BRITISH ORTHOPÆDIC ASSOCIATION

THE annual meeting of the British Orthopædic ssociation was held in Sheffield on Oct. 24 and 25, nder the presidency of Sir REGINALD WATSON-JONES.

THE WATER CONTENT OF THE NUCLEUS PULPOSUS

Mr. A. NAYLOR (Bradford) had studied experimentally he changes in pressure within the isolated intervertebral isc, excised with the bony endplates. Normal discs mmersed in water showed an initial slight fall of pressure ascribed to swelling of the annulus fibrosus), followed y a substantial increase caused by swelling of the ucleus, which reached its maximum size after fifteen ours. Immersion in normal saline usually caused less welling. These pressure changes were not observed in egenerate discs. Further experiments suggested that he swelling was due to osmotic changes, fluid entering hrough the endplates, which behaved much like a emipermeable membrane. Mr. Naylor believed that hanges in the water content of the nucleus pulposus night play an important part in the causation of back ain, and that when the annulus fibrosus was thin or lamaged, swelling of the nucleus due to an increase in ts water content might precipitate herniation.

THE LUMBAR DISC-LESION SYNDROME

Mr. J. R. ARMSTRONG (London) recalled that one of he cardinal features of the symptoms of protruded ntervertebral discs was their episodicity, the symptoms ubsiding and recurring, sometimes repeatedly, at varying ntervals. He discussed the pathological and mechanical actors in the disc and disc-root relationship that might ccount for these periodic variations. He had found evidence of at least twelve such factors, any one of which might operate in an individual case :

(1) final rupture of the annulus might occur suddenly from mechanical forces, and cause marked exacerbation of symptoms ;

(2) a nuclear fragment might become impacted and cause "locking" of the joint ;

(3) the size of a nuclear protrusion sometimes varied during movements and changes of position of the spinal column ;

(4) an existing tear of the annulus might extend, or might heal ;

(5) œdema added to the size of a nuclear protrusion in its early stages ; subsidence of this œdema would lead to decrease of symptoms (œdema might also affect the nerve-root) ;

(6) gradual shrinkage of a protruded nucleus led to spontaneous decrease of symptoms ;

(7) a nerve-root might become adapted to stretching ;

(8) the relationship between nerve-root and protrusion might vary ;

(9) a nerve-root might become elongated ;

(10) a nerve-root often became adherent, with consequent pain when the nerve was stretched by changes of posture ;

(11) permanent pathological changes might occur gradually within the nerve-root itself ;

(12) in the stage of degenerative arthritis, sudden exacerbations resulted from irritability of the intervertebral joint.

TREATMENT OF LUMBAR INTERVERTEBRAL DERANGEMENTS BY TRACTION

Dr. E. J. CRISP (London) said that although some years ago he was sceptical of manipulation in the treatment of intervertebral derangements, he had found that many patients were relieved, often dramatically, by sustained traction. He had designed an apparatus to exert traction on the lumbar spine without pulling upon the thorax or limbs. Traction up to 120 lb. was applied, without anæsthesia, usually for fifteen minutes. Careful measurements had shown that distraction of the spine did, in fact, occur. In a series of over 200 patients treated in this way the results had been good : 15 out of 17 patients with acute lumbago, 9 out of 12 with acute sciatica, and 2 out of 6 with pain after laminectomy were completely relieved ; and 50% of women with chronic back pain were improved. Experience had led him to believe that by no means all back pain or sciatica was due to prolapsed intervertebral disc. In many cases changes in the posterior joints, such as nipping of synovium between the facets, might be responsible. These were the cases that might be expected to respond well to non-operative treatment.

Sir REGINALD WATSON-JONES said that these three papers were particularly interesting because they represented respectively the experimental, the clinical, and the empirical approach. He questioned the significance of experiments in which the intervertebral discs were immersed in water rather than in physiological saline.

Mr. PHILIP WILES (London) said that he had practised manipulation in the treatment of patients with back pain and sciatica, at first with, but more recently without, anæsthesia. He thought that the dangers had been exaggerated. In only two cases had he precipitated an attack of acute sciatica—in each case, he thought, by hyperextension, which he now omitted from his routine. He agreed with Dr. Crisp that in many cases of back pain the underlying pathology was not directly concerned with the intervertebral disc.

Prof. B. L. MCFARLAND (Liverpool) thought that both forced flexion and forced extension were dangerous, and should be avoided. Traction might relieve about 25% of patients with clinically doubtful disc lesions.

Mr. JOHN CHARNLEY (Manchester) drew attention to the unique structure of intervertebral discs. The nucleus consisted almost entirely of acellular matter, which behaved almost like a chemical substance ; thus, it could be dried and subsequently restored almost to normal by immersion. He believed that many pains in the back might be due to temporary pressure changes in discs. Further research on this aspect of the problem was required.

DIRECT SKIN FLAPS AND TUBE PEDICLES

Mr. WILFRED HYNES (Sheffield) described the management of three difficulties that were commonly experienced in skin-grafting by flaps and tube pedicles. One important difficulty was the length of time taken up by the various stages of transferring a flap—often about three months in all. By a special test which indicated the degree of vascularisation at the pedicle of the flap, he had found it possible to reduce the waiting time between stages, sometimes to less than half the time previously thought necessary. In this test atropine (gr. $^{1}/_{25}$) was injected into the flap after clamping the pedicle to be divided. If the effects of atropinisation (tachycardia and dry mouth) were observed within forty minutes, the pedicle could be divided safely. Another difficulty was to decide how much additional time should be allowed for revascularisation when part of the inset was lost by necrosis. Here again the atropine test gave a good indication of the viability of the flap, and it had shown that the blood-flow through a pedicle might be surprisingly good, despite necrosis of a considerable part of its area. A third serious difficulty was the "blue flap," a condition in which, within a few minutes of the operation, cyanosis began to appear around the inset of a flap, and was followed by necrosis which gradually spread and might involve loss of the whole flap. This complication was due to thrombosis of vessels in the flap, the capillary pressure being sufficient to drive blood in, but not to expel it. He had found that if the blood was kept moving in and out of the flap, thrombosis might be prevented or minimised. This could be achieved in some cases by altering the posture of the patient every ten minutes so that blood flowed in and out of the flap by gravity ; or by intermittent venous occlusion by a pneumatic cuff applied to the limb proximal to the flap.

EARLY TREATMENT OF THE BLADDER IN PARAPLEGIA

Dr. A. G. HARDY (Sheffield) emphasised that the problems of paraplegia must be regarded as a whole rather than individually. Thus, successful management of the bladder was closely related to the efficient prevention of sores, sepsis, and prolonged immobility, all of which reacted unfavourably upon the urinary system. Exceptional care in nursing was essential, and the diet should include a high fluid intake. *Management* of the bladder should be designed not only to prevent complications, but also to encourage coördinated reflex activity, which often took a long time to develop and was dependent upon an intact lower segment of the cord. The method favoured was constant drainage through a urethral catheter, changed weekly by a strict aseptic technique. The urine drained continuously into a bottle beneath the bed, except for periods when the tube was clipped for retraining reflex activity. Irrigation was carried out by the closed method. Antibiotics were used as required, but infection was gauged more by clinical than bacteriological evidence. The residual urine was carefully observed, and each week the catheter was left out for a trial period to assess the progress of reflex activity. The duration of catheter drainage varied, being longest after complete transection in the lumbar region; it had never been required for more than thirty-two weeks.

SURGICAL TREATMENT OF DUPUYTREN'S CONTRACTURE

Mr. H. J. RICHARDS (Oswestry) described the surgical treatment of Dupuytren's contracture. He recommended excision of the whole palmar fascia through incisions in the skin creases, with mid-lateral extensions in the fingers. In the typical Dupuytren's contracture there was no actual loss of skin, but simply shrinkage secondary to contracture of the underlying fascia. Once the fascia was removed the skin would stretch again if given time. Skin-grafts were unnecessary. After operation a firm massive pressure dressing was applied to the palm, and the hand put at rest in a posterior plaster shell, no attempt being made at that stage to overcome the original deformity. The sutures were removed on the fourteenth day, and when the wound was fully healed active extension of the fingers began. Correction of the deformity was a gradual process sometimes occupying many weeks or months.

Mr. J. I. P. JAMES (London) confirmed, from his series of 90 cases of Dupuytren's contracture treated by a similar operation, that there was no need at all for skin-grafting. If the operation *and the after-treatment* were correctly done "there was nowhere to put the skin." Nearly all patients regained full movement of the fingers.

SUPRACONDYLAR "Y" FRACTURES OF THE HUMERUS

Mr. E. MERVYN EVANS (Swansea) recalled that in this fracture the olecranon was forced upwards between the humeral condyles. The injury was usually one of adolescents or young adults. Full operative reduction and internal fixation had given disappointing results with consequent elbow stiffness. Mr. Evans suggested a simpler operation in which the fracture was converted into an ordinary supracondylar fracture, which was relatively simple to manage. His method was to fix the medial and lateral condyles rigidly together by a transverse screw, with minimal disturbance of the muscles and joint capsule. Thereafter the supracondylar fracture was reduced by manipulation and immobilised in plaster in the usual way.

PRIMARY INTERNAL FIXATION OF COMPOUND FRACTURES

Mr. F. R. ZADIK (Wigan) said that in closed fractures that were unstable the value of internal fixation was accepted, but that the principle of primary internal fixation of compound fractures was controversial. He believed that many advantages accrued from primary internal fixation, provided the wound did not break down. Wound breakdown was caused either by infection or by tension; infection could be prevented by careful and radical excision of non-viable tissues, and by the use of antibiotics. He had used primary internal fixation in 24 open fractures in which the fragments appeared unstable (tibia and fibula 13, ankle 3, radius and ulna 8): 19 wounds, healed by first intention; 4 broke down (3 from tension, 1 from infection); and 1 wound was not closed completely. His results showed that union occurred in an average time which was not significantly longer than that for simple fractures.

Mr. NORMAN ROBERTS (Liverpool) said that he did not accept the necessity for internal fixation of tibial fractures even in closed injuries. If it was accepted for simple fractures, he saw no objection to extending it to open fractures.

Mr. C. H. CULLEN (Wigan) accepted the advantages of internal fixation for tibial fractures, and thought that Mr. Zadik had shown it to be safe in open fractures.

Mr. H. OSMOND-CLARKE (London) deplored the routine use of internal fixation for all fractures, and thought that every fracture should be treated on its merits. Many unfortunate results of internal fixation of open fractures had been seen during the war.

Mr. WILES emphasised the danger to the limb if aseptic precautions were unsuccessful and the wound broke down.

Mr. T. J. FAIRBANK (Cambridge) thought that the problem rested on the outlook for healing of the wound, as judged from the surgeon's experience. If it seemed certain that primary healing could be obtained, internal fixation was justified.

Mr. J. N. WILSON (Cardiff) and Sir HARRY PLATT (Manchester) thought that the method was justified in certain selected cases.

Mr. J. C. SCOTT (Oxford) agreed that much depended upon the likelihood of healing of the wound, which was the matter for prime consideration. Only exceptionally was internal fixation justified at the stage when the wound was open.

Mr. O. J. VAUGHAN-JACKSON (London) suggested that the practice might become more hazardous in the future because of the increasing incidence of resistant organisms.

Sir REGINALD WATSON-JONES, summing up the discussion thought that the wisdom of internal fixation depended upon the nature of the wound and of the fracture. If the wound was grossly contaminated, the addition of further foreign material was quite unjustified. On the other hand, if the wound was such that primary healing, with suitable management, seemed certain, there could be no harm in internal fixation of the fracture when such a step was advisable on mechanical grounds.

THE DISLOCATED HIP WITH FRACTURED ACETABULUM

Mr. E. A. NICOLL (Mansfield) reported observations on 144 cases of dislocation of the hip-joint, contributed by a number of surgeons forming a clinical research group of the association. A fracture of the acetabulum, complicating traumatic dislocation of the hip, might have three effects:

(1) it might cause instability of reduction;
(2) a fragment of bone might be included within the joint;
(3) the incidence of late osteo-arthritis and of sciatic-nerve lesions was increased.

Instability was likely only when a large segment of the acetabulum was displaced. Treatment should be by immediate operative reduction and fixation by a screw. Inclusion of a fragment within the joint was exceptional, and occurred only with small fragments. Sciatic palsy was three times as common after fracture-dislocation as it was after simple dislocation. In 4 out of 5 cases the nerve lesion was incomplete, affecting almost invariably the peroneal fibres; the lesion was always in continuity, but the prognosis for recovery was poor (5 out of 13 in the series studied).

Sir **REGINALD WATSON-JONES** emphasised the importance of immediate reduction of displaced acetabular fragments in cases of sciatic-nerve palsy; the nerve was usually stretched over the sharp margin of the tilted bone, and recovery was jeopardised by delay in reduction.

BIOCHEMISTRY OF BONE

Prof. **H. A. KREBS**, F.R.S. (Sheffield), said that whereas early studies of bone had been concerned with its composition, more recent work had dealt with its activity. Experiments in which radioactive isotopes were introduced into the body had shown that bone, in common with other living tissues, was in a dynamic state—i.e., the material of which it was made was constantly being changed. In normal circumstances removal and resynthesis proceeded at the same rate, so that there was no apparent change in structural composition. The rate of the exchange varied with different tissues, being relatively rapid in those with high metabolism: thus, in the liver some constituents had been shown to be replaced completely within a matter of days, whereas in bone the process was much slower.

TUBERCULOSIS OF THE ELBOW-JOINT

Mr. **J. N. WILSON** (Cardiff) reviewed 31 cases of tuberculosis of the elbow joint. The disease was commonest between the ages of ten and thirty. He recognised 4 types: synovial, extra-articular, coronoid, and massive; and the massive type was the most common. Sinuses and tuberculous lesions elsewhere were common complications. Conservative treatment by immobilisation in plaster for an average of eighteen months was the standard treatment. Streptomycin had been available for only 4 cases, in which it seemed to help resolution. When the disease was quiescent the elbow was suitable for light exercise without support, but if heavy work was necessary a block leather splint was provided. Arthrodesis had been performed in 3 cases in which there had been persistent pain or recurrent flares. Three other elbow-joints, all with sinuses, underwent spontaneous bony fusion.

SPASTIC EQUINUS DEFORMITY

Mr. **G. A. POLLOCK** (Edinburgh) said that in cases of spastic diplegia the commonest deformity requiring operative correction was equinus, and he described the operation of lengthening the gastrocnemius tendon. Recurrence after operation was frequent, and might be due to inadequate lengthening of the tendon, to lengthening of the whole tendon when the contraction was confined to the gastrocnemius component, or to inadequate splintage after operation. When only the gastrocnemius component of the calf group was contracted, as determined by the knee-flexion test, lengthening of the affected tendon alone was satisfactory; it had the advantage of attacking the trouble at its primary site, of preserving the strength of the calf muscles, and of avoiding the risk of later calcaneus deformity. He illustrated the technique of the operation by a film.

FRACTURE-DISLOCATION OF THE THORACOLUMBAR SPINE

Mr. **F. W. HOLDSWORTH** and Dr. **A. G. HARDY** (Sheffield) described and demonstrated in detail their routine examination of patients with fracture-dislocation of the thoracolumbar spine complicated by paraplegia. They showed how, from simple clinical tests and radiographs, the upper limit of the lesion, the condition of the nerve-roots, and the condition of the distal segment of the cord could be accurately analysed. They emphasised the importance of certain reflexes, especially the bulbocavernosus and the anal skin reflex, in indicating activity in the distal part of the cord. The technique of nursing, by which 50 patients had been successfully treated without a pressure-sore developing, was also demonstrated; after such operative stabilisation of the spine as was required, the patient was nursed on pillows and was turned methodically every two hours. Patients were shown with fracture-dislocations at the D12 to L2 level illustrating:

(1) complete cord lesion and complete root lesion;
(2) complete cord lesion with partial root escape;
(3) complete cord lesion with total root escape.

The function and gait that could be hoped for in each group of patients was shown. The impressive results emphasised the importance of treating paraplegic patients in centres specially equipped and staffed for their care.

Reviews of Books

Diseases of the Ear, Nose, and Throat

Editor: W. G. SCOTT-BROWN, C.V.O., M.D., F.R.C.S., ear, nose, and throat surgeon, Royal Free Hospital, London. London: Butterworth. 1952. Vol. 1. Pp. 756. Vol. 2. Pp. 639. 8 guineas per set.

THE demand for a comprehensive British textbook of otolaryngology will be largely satisfied by the inclusion in this new work of an up-to-date and authoritative account of diseases of the ear. The task of authorship has been shared by 32 contributors, and the personal views of many leading specialists have been supplemented by an extensive review of recent literature. The sections on anatomy are written by anatomists, those on physiology by physiologists—an experiment well justified by the results. The authors of the chapters on allergy, pharyngitis, perceptive deafness, and deafness in children present their difficult subjects particularly clearly. Operative technique is well described; and such related subjects as plastic surgery (by a plastic surgeon), anæsthesia (by an anæsthetist), diseases of the lacrimal apparatus, and the pharyngeal manifestations of general disease, each get a separate chapter. There is too little information for the specialist, however, on some important topics, such as nasal polypi. Divergences of opinion are remarkably few, but where they exist they make for stimulating reading. With a few notable exceptions the reproduction of skiagrams is poor, but the illustrations of clinical material and pathological specimens and sections are very good. The chapter on speech defects is confusing and has no bibliography, and there are inaccuracies in the chapter on nervous diseases of the larynx. But this is a book that fulfils its purpose well, and should be much used.

History of the Royal Medical Society

JAMES GRAY, M.A., F.R.S.E. Editor: DOUGLAS GUTHRIE, M.D., F.R.C.S.E., lecturer in history of medicine, University of Edinburgh. Edinburgh: University Press. 1952. Pp. 355. 42*s*.

To anyone who does not know the Edinburgh Medical School this may seem at first a puzzling book. The title of the society, the royal warrant, the frontispiece of an elderly doctor, the early illustration of the society's house, all suggest a postgraduate body similar to the Royal Society of Medicine or the Liverpool Medical Institution. But it was founded by six students, and was (and is) essentially a student society, though it caters also for young graduates, from whom the presidents have usually been derived. It must be almost unique for a student body to own its own house and obtain a royal warrant; and its meetings and discussions must have had immense influence in teaching students to speak in public and think quickly in debate: indeed, Sir Robert Hutchison tells us that it was one of the most formative influences of his undergraduate days.

In the main the book is concerned with the distinguished men who have been members, most of whom are accorded short biographies which interfere somewhat with the story of the society's development. Cullen, Syme, Liston, and Lister are good examples, and there were others who earned fame away from medicine—Oliver Goldsmith, Sidney Smith, Charles Darwin, and Jean Paul Marat among them. Indeed, the astonishing feature is the very large number of famous men who in their youth were members of this flourishing body. Osler said in 1907: "Looking over the list of members since 1737 I was prepared of course to find the names of many of the great men of the profession, but I did not expect to find a list of such extraordinary distinction. I doubt if there is any other society in the world, except perhaps the Royal Society of London, with such a roll of honour." This book adds great prestige to a unique society.

Statistics for Medical and other Biological Students

L. BERNSTEIN, B.SC., M.R.C.S., senior lecturer in physiology, London Hospital Medical College; M. WEATHERALL, M.A., D.M., B.SC., senior lecturer in pharmacology, London Hospital Medical College. Edinburgh: E. & S. Livingstone. 1952. Pp. 180. 18*s*.

Elementary Medical Statistics

DONALD MAINLAND, M.B., D.SC., F.R.S.E., F.R.S.C., professor of medical statistics, division of medical statistics, the Department of Preventive Medicine, New York University College of Medicine. Philadelphia and London: W. B. Saunders. 1952. Pp. 327. 25*s*.

TEXTBOOKS which seek to introduce the medical student to statistics are becoming infinite in their variety. Authors have to steer between the Scylla of the statistical "cook-book," which merely gives arithmetical recipes for the various technical tests of significance with no attempt at their logical justification, and the Charybdis of a too rigorous approach to their mathematical background. Dr. Bernstein and Dr. Weatherall have veered towards the latter, and the ordinary clinician may be daunted by four pages of mathematical symbols and their definition in the introductory part of the book. The younger student, fresh from the school bench, may be able to assimilate these, and, fortified by a clear discussion of the logic of scientific method, may proceed to a detailed study of the laws of probability and the various descriptive measures of frequency distributions.

An orthodox development of regression and correlation with lucidly worked examples leads to a helpful discussion of the use of transformations in dealing with non-normal distributions. Such distributions often occur in practice but need modification before they can be handled by the usual techniques. Probit analysis, which is becoming increasingly important in the standardisation of biological medicaments, is briefly discussed, and the last five chapters are devoted to an account of the commoner difficulties and fallacies in the design of experiments and the interpretation of their results. Throughout, the practical applications are kept in view, although occasionally obscured by a presentation which is too formal for the ordinary medical student and yet too imprecise for the mathematically sophisticated.

For the complete novice an even simpler introduction is required, but the book may well be useful to initiates who want a fuller description of statistical methods applied to laboratory and clinical work, particularly in pharmacology.

Dr. Mainland's text is less ambitious and in some ways more successful.

Much more space is given to the systematic appraisal of evidence, with emphasis on the interpretation of differences in frequency of events. The concept of the confidence limits of a percentage, and of the differences between percentages, forms the basis for an elementary account of the principles of the clinical trial. Despite some apparent contradictions in the sections dealing with pairing and the calculation of the numbers required to confirm preliminary results, this section should prove helpful to the experimentally minded clinician. These ideas are then translated into tests of significance in measurement. The t-test for the difference between means leads naturally to the analysis of variance and measures of concomitant variation, but the latter subject is treated only cursorily. A most valuable discussion of the clinical relevance of statistical ideas indicates the importance of variability between individuals in the assessment of "normality" and between technicians in the reliability of blood-counts. Dr. Mainland's enthusiasm for Fisherian developments in the field of small-sample technique and experimental design makes him perhaps less than fair to the value of the methods used and results obtained by workers in public-health statistics; indeed his description of the life-table suggests a certain unfamiliarity with this aspect of statistical studies. At every stage, understanding is tested and enhanced by stimulating questions and answers.

No elementary text could be expected to cover the wide field of statistical methods, but the selection of topics discussed and the simple manner of their discussion make this book a useful primer in the numerical approach to clinical medicine.

The Threshold of the Abnormal

A Basic Study of Psychopathology. WERNER WOLFF. London: Medical Publications Ltd. 1952. Pp. 473. 30*s*.

THIS book contains a vast amount of information, and copious erudite references, but hardly a chapter which suggests a fresh outlook on familiar territory. In fact it has the usual faults of a compilation which make one regret that it has been allowed to absorb the energies of an able and original mind. If no-one had written a textbook of abnormal psychology before, this would be a treasure-house, an invaluable repertory: but at this time of day its appeal must be to the author's students and the many porous people who soak up anything psychiatric. Apart from these serfs and sponges, the readers to whom the book will be useful are those who want to find or check references, and are therefore able to draw sustenance even from such a sentence as "Many theories have been proposed to explain the phenomenon of emotion. 7, 11, 12, 24, 25, 45, 109, 111, 115, 143, 198." Such sentences abound, but unfortunately the numbers are not always easily decipherable without a loupe.

The Specialties in General Practice

Editor: RUSSELL L. CECIL, M.D., professor of clinical medicine, emeritus, Cornell University Medical College, New York. Philadelphia and London: W. B. Saunders. 1951. Pp. 818. 75*s*.

THIS book, written by 14 specialists of professorial rank in various North American universities, sets out to supply the general practitioner with a guide to the specialties. "In . . . cases," says the editor, "which come within the field of a definite specialty the practitioner is expected to make at least a tentative diagnosis, to indicate without delay the best course of therapeutic procedure or to refer the patient to a specialist." It is the implied aim of the book to help him to do these things.

The chapters are, naturally enough, of unequal value. In some the author succeeds in seeing his specialty through the family doctor's eyes and gives him the information he genuinely needs; in others he sees it through his own eyes, displays a predilection for the rare, and describes and illustrates elaborate techniques outside the practitioner's range. In many sections there is little discrimination between the rare and the common. The numerous illustrations, from photographs, X-ray films, and diagrams, are uniformly good, but the same cannot be said of the writing. The words spent in avoiding the simple imperative must number thousands in the course of the volume. Transcription of these passages into terse and lucid English would make room for at least one new section.

Handwriting: a Personality Projection (Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 149. 27*s*. 6*d*.).—Few doubt that so individual a characteristic as a man's handwriting gives indications of his personality, and that some people are more skilled than others at the process of divination. Lucid statements of the method, scope, and reliability of "graphology" are, however, very rare. This book by Mr. Frank Victor, PH.D., is a serious attempt to provide the necessary information in a brief form, with references to published work, especially the copious German output of the 1930s. Unfortunately it does not succeed; since, in spite of his just emphasis on release, tension, and energy, Dr. Victor cannot validate the relations he asserts between spatial movements and their symbolism. Failing to provide this, he remains a moderate apologist for the intuitive procedure in the use of which, it may fairly be assumed, he and some other graphologists are highly gifted.

THE LANCET

LONDON: SATURDAY, NOV. 8, 1952

Prematurity and the Obstetrician

THE wastage of fœtal and infant life by stillbirths and neonatal deaths has never attracted as much attention as deaths beyond early infancy. Yet in England and Wales during 1949 there were 31,053 such deaths, compared with 727 maternal deaths and 3789 deaths on the roads. Among the causes of this loss of fœtal and infant life, prematurity is paramount. CROSSE[1] found in Birmingham that in almost half the stillbirths and over half the neonatal deaths the birth weight was under 5½ lb. BAIRD[2] showed that the death-rate among premature infants was ten times that among infants of mature weight; and the Registrar-General's reports make it clear that in England and Wales prematurity accounts for some 40% of neonatal deaths.

For the premature child the first forty-eight hours of life are the most critical; 65% of neonatal deaths take place in this period. Any substantial reduction in the rate of stillbirths and early neonatal deaths among premature infants will depend on either preventing premature birth or reducing the hazards of delivery. Unfortunately, our knowledge of the causes of prematurity is incomplete; and often no satisfactory explanation can be found. CROSSE[1] showed that "cause unknown" accounted for 36% of the large series which she investigated, and BAIRD[2] found that in one group this figure was as high as 52%. Among the conditions known to be associated with premature birth the two most prominent are toxæmia of pregnancy and twins. Other causes—for example, syphilis, diabetes, fœtal abnormality, and the induction of labour for reasons other than toxæmia—are much less common. Work in Australia[3] has shown that careful antenatal supervision can go far towards preventing eclampsia and reducing pre-eclampsia. The Women's Hospital, Crown Street, Sydney, had an average of 9 eclamptics per year in booked cases until 1947; but in 1950–51 there was not a single instance of this complication in such cases. This success has been achieved by an elaborate check of all antenatal patients to ensure regular attendance; by paying close attention to early warning signs of toxæmia, such as increased weight-gain and finger œdema; by controlling weight with a high-protein, high-vitamin, low-carbohydrate diet; by giving daily advice and lectures on diet to new patients; and by more frequent attendance and early admission to hospital of all suspect cases. With eclampsia completely prevented and serious pre-eclampsia uncommon, the induction of premature labour has been correspondingly reduced. There is evidence, too, from other sources that improvement in the diet and nutrition of the pregnant woman not only helps to prevent prematurity from toxæmia, but also reduces the number of unexplained premature births. BAIRD[2] has shown these to be more common in the lower-income groups where diet is poor than in the better-to-do patients. Other nutritional surveys have revealed that the number of unexplained premature births falls when poor diets are brought up to the required standard. Much improvement in this aspect of antenatal care is still possible. In many clinics patients are commonly given extra iron and vitamins—the Ministry of Health encourages this practice by supplying cod-liver oil and orange juice for the expectant mother—but they rarely receive any instruction on how to correct their diets in order to combat anæmia and vitamin deficiency. If these abnormalities are attacked early in pregnancy by proper advice, the iron pills need not be prescribed (even when they are prescribed they are not always swallowed), nor will the urgent intravenous-iron therapy or blood-transfusion be so often needed in late pregnancy. Could not instruction on diet be as regular a feature of antenatal care as that on relaxation? In industrial areas anæmia and ill health are more of a problem than failure to relax during labour. Again, could not some of the time spent in palpating the patient's abdomen be better used in talking to her about matters of health? We would do well to pay no less attention to the mother during pregnancy than to the presentation and position of the fœtus.

Whatever the improvements in antenatal care, however, there will still be some premature births; and in these special treatment is necessary. The respiratory centre of the premature child is particularly vulnerable to depressant drugs, and its fragile skull gives poor protection against intracranial damage. The drugs ordinarily used to relieve the pain of childbirth may delay respiration or prevent it from being fully established. Undoubtedly the safest method is local infiltration of the perineum with, say, 1% procaine, which may be combined with analgesia by inhalation of trichlorethylene just as the child is being delivered. Caudal and spinal analgesia are also said to be excellent in this type of case; but they carry a greater risk to the mother. Even more serious is the risk of fatal intracranial hæmorrhage; resistance to the head from a normal perineum, for instance, may cause a tentorial tear—a danger that has led to prophylactic episiotomy. RUSSELL and BETTS[4] have analysed the effect of this operation in premature delivery, and have shown that it lowers mortality significantly. Their findings also suggest that mortality may be further reduced by applying low forceps, which may protect the child from damage, especially when this procedure is combined with wide episiotomy. Formerly most obstetricians held that in premature delivery forceps should not be applied.

Epidemiological Attack on Tuberculosis

BECAUSE of advances in chemotherapy and thoracic surgery the main emphasis in tuberculosis has centred lately on treatment of the established case. The epidemiology of the disease has not been neglected, but more thought might have been given to new methods of prevention and control if advances in treatment had been less striking. The value of supervising family contacts is fully recognised[1]; but with few exceptions the epidemiology outside the household has not been studied with an eye to prevention. Exceptions are the "mass" methods of photofluorography and, on a trial basis, inoculation with B.C.G. The study of a complete community in a South Wales mining valley[2] should in a few years increase our knowledge of the epidemiology of tuberculosis in a wider field; and STEWART's[3] studies of infection in factories, and occasional investigations of tuberculin sensitivity in school entrants to indicate sources of infection, are other instances of epidemiological methods extended beyond the household.

GEDDE-DAHL[4] has made an environmental study by the method of "tuberculin matriculation," by which he means the continuous tuberculin testing of the whole population. This is divided at the start into tuberculin-positive and tuberculin-negative groups; the tuberculin-negative group is periodically retested with tuberculin, while the positives and converters are kept under radiological observation "until the risk of disease is minimal." He has applied this technique to a rural community of 6500 on the west coast of Norway where he held the post of public medical officer and was in charge of the tuberculosis diagnostic centre, as well as doing most of the general practice. The percentage tuberculin-positive in each age-group was much lower than that found in this country by the Medical Research Council.[5] At age 15–19, 20% were positive in completely rural areas, and 30% in a small town, compared with over 50% in this country. The proportion positive reached a maximum of 70–90% at age 45–54, and the level fell somewhat in older age-groups. In this context GEDDE-DAHL possibly underestimates the importance of reversion—i.e., the change from the tuberculin-positive to the tuberculin-negative state. The annual reversion-rate may be quite low, but the majority of adults are positive, and a low conversion-rate may thus balance an appreciably higher conversion-rate in a small proportion of the population. Thus in a group, 90% of whom are tuberculin-positive, an annual reversion-rate of 1% will exactly balance an annual conversion-rate of 9%. The conversion-rates observed by GEDDE-DAHL ranged from 1% for the age-group 7–10 years to 5% at 20–24 years, falling to about 4% in older age-groups.

Anyone who underwent tuberculin-conversion was closely observed, and the source of infection was also diligently sought. Because the community was scattered and isolated the chain of infection could often be traced with fair certainty. During the study 274 conversions are known to have taken place. Even in children the infection was intradomiciliary in only half the cases; at age 15–19 only 1 infection in 5 was intradomiciliary, more than half were from known extradomiciliary sources, and just over 1 in 4 from unknown sources. As GEDDE-DAHL points out, when there are many sources of infection a high proportion of children will be infected at home; but as the number of sources of infection falls, infection is postponed until the age of increasing social and work contacts. GEDDE-DAHL also found a connection between the source of infection and the likelihood of tuberculous disease in its widest sense. Of all converters 48% showed some evidence of tuberculous disease; the percentage was 76 for those with intradomiciliary exposure, 41 for those with known extradomiciliary exposure, and 31 for those in whom the source of infection was unknown. The report does not mention the possible influence of genetic relationship with an infectious case, though from a table it appears that over 70% of those infected within the household were related to the infector. GEDDE-DAHL also concludes that patients with uncomplicated primary tuberculosis rarely infect others, though gastric washings may show tubercle bacilli. The type of case mainly responsible for infecting others was the well-established one which perhaps had been recognised elsewhere but had not remained under supervision. Such situations are by no means unknown in this country, and GEDDE-DAHL's plea for more complete notification and greater continuity in control of tuberculosis should find an echo here. The "good chronic" with occasionally positive sputum was a less important source of infection, even of household associates, than might be expected. At the other extreme was a heavily sputum-positive young man who infected 12 or 15 tuberculin-negative people in the course of one evening's singing and dancing at a Christmas party in a crowded schoolroom; even here, however, a much larger number of tuberculin-negative people were present but were not infected. In this survey the *epidemiological incubation period*—i.e., the interval between first infection of a person and his being a source of infection to others—was unknown in 15 cases, at least 1–4 years in 8 cases, at least 5–9 years in 12 cases, and more than 9 years in 7 cases. The close supervision of converters, with treatment when necessary, no doubt helped to postpone the chances of infection being spread.

GEDDE-DAHL recognises that tuberculin matriculation is not feasible in urban communities with high infection-rates—there would be too many untraced infections. Under such conditions mass radiography and preventive inoculation must be the main methods of epidemiological control. There is, however, every reason to agree with GEDDE-DAHL that, as tuberculosis decreases, a point is reached at which mass radiography is wasteful because so many of those examined in this way have never been infected. Similarly in regard to preventive inoculation, a point is reached at which the risk is so slight that mass inoculation is not justified, especially as it spoils the field for epidemiological control by tuberculin matriculation. In this country such ideas may seem utopian; but our methods of investigating and controlling outbreaks of acute infectious diseases, such as typhoid fever and smallpox, would have seemed equally utopian in the

19th century. We must be prepared to supplement our efforts to control the disease in the patient and his household by really effective control of the infection in the community.

Identification of Blood Sera

The differentiation of the blood sera of animals of various species is sometimes important for incriminating (or even exculpating) both human criminals and insect vectors of disease. The distinctive constituents of serum which differ from one species to another are the proteins; but, whereas simple chemical compounds can be distinguished with relative ease by chemical and physical methods, the giant protein molecules are very difficult to identify. The various blood-serum proteins all have very much the same chemical composition; they are all built up from the same amino-acids, and many of their physical properties are almost identical. Nevertheless the biological properties of separated protein fractions differ widely; for example, antibody proteins occur in the globulin fractions of serum and never in the albumin. Electrophoretic methods of separation, developed largely by the use of the Tiselius[1] apparatus, make use of slight differences in the distribution of basic and acidic groups in the side chains of the protein molecule, and by this means at least eight different serum-protein fractions have been prepared. Even this method does not yield chemically homogeneous preparations, and Hewitt[2] has shown that the albumin fraction can be further separated into seroglycoid, a protein containing a high proportion of polysaccharide, and crystalbumin, which unlike the other serum-proteins is carbohydrate-free. During the late war large quantities of human plasma were available from blood banks, and this enabled Cohn[3] and his colleagues to develop carefully controlled protein-fractionation methods using organic solvents at low temperature. As a result of this work, gamma-globulin and albumin fractions are now made on a commercial scale, but even so these advances in our knowledge of the chemistry and physics of proteins have not yet made it possible to differentiate between the serum-proteins of different species of animals. On the other hand, immunological methods of differentiating them have been available for fifty years. When an animal is injected with a foreign protein, antibodies appear in the blood, and if the animal's serum is mixed with a solution of the foreign protein a precipitate is formed. Bordet[4] in 1899 found that the blood serum of one species of animal acts as a foreign protein when injected into another species and it gives rise to precipitin formation. This phenomenon was applied to the study of the relation between zoological species by Nuttall[5] in 1904, and his work has remained of fundamental importance. He found that, when the immune serum was mixed with different foreign sera, the amount of precipitate formed was greatest when the foreign serum was of the same species as the serum used for immunisation; less precipitate was formed with sera of different but closely related species; and least of all when the sera of distantly related species were tested. Thus the serum of a rabbit immunised with human serum gave most precipitation when mixed with human serum, less with anthropoid ape serum, still less with that of a monkey, and least with dog and cat serum.

As the test can be carried out with very small amounts of material, it is used in medicolegal work for the identification of blood stains, when it will indicate the animal species from which the blood came. The precipitin technique has also been used in tracing insect vectors of disease. In order to trace and control the spread of diseases transmitted by blood-sucking insects it is necessary to know what are the principal and supplementary hosts whose blood the insects suck, and hence the animal species concerned in the infection.[6] To identify the blood which the suspected insects feed on, the precipitin technique has been used for the past thirty years as a means of examining the contents of the insect's stomach and crop. The experimental difficulties are considerable, for the insects themselves and their alimentary canals are small, the visceral contents are minute, the blood may have been largely digested before the insect is caught, and the original meal of blood is often small. The task of recognising the origin of bloods when the insect has fed on animals of several species is so difficult that every possible perfection of technique must be explored, as Weitz,[7] working under the auspices of the Colonial Research Committee, has lately done. It is perhaps surprising to find how comparatively little present-day technique differs from that used in the original work of Nuttall. Some of the criticisms made by Landsteiner[8] about the early work remain valid. Although blood serum consists of at least eight different protein fractions, the antigen used for preparing the specific sera is still whole serum, which gives rise to a multiplicity of antibodies in the immune serum. Though the work of Dean and Webb[9] on the optimum proportions of antigen and antibody, and the quantitative technique developed by Heidelberger and Kendall,[10] carried matters forward, the methods of the early workers are still in common use today, and it is a tribute to their acumen that their conclusions have stood the test so well.

Changes in General Practice

The Ministry of Health announces that the new arrangements, proposed by the Working Party,[11] for distributing the central pool to general practitioners in the National Health Service will come into operation early next year, probably during the quarter beginning April 1. The reduced limits to be set on the size of practitioners' lists will apply from the same time, but doctors who have more patients than the limits allow will be able to adjust their lists gradually over a period of a year up to April 1, 1954. The Ministry points out that practitioners who now employ assistants may like to gain the advantage of the new basis of payment for partnerships by taking them as partners before April 1, 1953. Under the revised limits, a member of a partnership will be allowed 4500 patients, provided the average for the practice is not greater than 3500; and for a permanent assistant the maximum will be 2000.

Annotations

SCHOOL DENTISTRY IN SCOTLAND

AN official report from Scotland[1] comments trenchantly on the failure of the school dental service to measure up to its task:[2]

> "At the present time the service is quite incapable of coping with the amount of dental disease in school children and the immense amount of treatment necessary cannot be overtaken. Only about one-sixth of the total school population receives treatment in a given year and much of this treatment is the extraction of aching teeth, leaving other teeth in a diseased condition."

In 1950 only 227,776 children of 785,380 on the school registers were inspected, and of those inspected no more than 115,085 received dental treatment of any kind.

> "It is clear that the ravages of dental decay are outstripping the meagre forces attempting to hold them in check. There is a further factor which accentuates the evil effects of insufficient dental care and that is, that whereas during the war years the incidence of dental decay was steadily declining, there has been a strong tendency in the reverse direction in recent years. Children's teeth now require more attention of a reparative nature than they did some years ago."

The report refers to a memorandum submitted by the subcommittee after it had considered the report of the United Kingdom dental mission on New Zealand school dental nurses.[3] It was then estimated that 500 dentists would be required for an efficient preventive dental service for children and expectant and nursing mothers in Scotland. In view of the impossibility of recruiting so many dentists, the subcommittee had then recommended the use of dental ancillaries similar to the New Zealand dental nurses. The present report reiterates this recommendation as an essential step in building up a preventive dental service in Scotland, and suggests that probably 200 dentists and 600 ancillaries would be required for the complete staffing of such a service. This suggestion, by a committee of dentists, may be set against some of the objections to dental ancillaries which are raised in our correspondence columns this week.

The report also recommends that the preventive services should make every effort to impress on mothers and school-children the importance of oral hygiene and sound nutrition.

BRONCHITIS

IN a survey of illnesses encountered in general practice in Sheffield, Pemberton[4] found that bronchitis was the commonest condition for which patients sought advice, and, as he remarked, "although the diagnosis of 'bronchitis' is not always precise, the condition or group of conditions to which it refers is clearly of great medical and social importance. . . ." Moreover, the treatment of chronic bronchitis is so unsatisfactory that any information which might help to prevent it would be welcome. In a search for such information Pemberton[5] has made a study of the Registrar-General's statistical reviews. Men are at all ages more vulnerable than women, but particularly after the age of 40. The first year of life is one of peculiar danger to both sexes, but again males predominate. The importance of social conditions is shown by the fact that the standardised mortality-ratio for bronchitis is five times greater among the unskilled workers of the Registrar-General's class v than among the professional and managerial members of class I; and when infants alone are considered the difference is even greater. It is rather surprising to find that outside the large industrial towns, people in the south of England seem no less prone to serious bronchitis than those in the north. It is hard to distinguish the effects of climate on bronchitis from those of other environmental conditions, but temperature alone may not be as important as is commonly believed; and Waddy[6] has recently argued convincingly that, in epidemic respiratory infections at any rate, a low absolute humidity may be of greater significance. Among adults the brunt of the disease falls on men in the second half of life who live in the industrial towns. The countryman is relatively immune. The greatest dangers to the town-dweller seem to lie in overcrowded houses, factories, buses, and trains, but atmospheric pollution and specific occupational hazards must also play a part. The figures on which Pemberton bases his assessment of the occupations carrying a special risk of bronchitis are twenty years old and may not apply today, but they show that respiratory illness is (or was) outstandingly common among potters and cotton strippers, probably because they are exposed to a great deal of dust, and among foundry furnacemen, probably because they are subjected to extreme changes of temperature and humidity.

Clearly, a variety of social and industrial conditions are aggravating, if not causing, bronchitis, and this extremely troublesome disease is one of several that we may reasonably hope to subdue, or at least to modify, by further improvements in living conditions both at home and in the workshop.

INSULIN SUPPLY

ARRAIGNED, if that word be not too violent, before the Monopolies Commission, the manufacturers of insulin leave the court without a stain upon their characters. Oversimplified into the form of question and answer, the commission's report[7] would run somewhat as follows.

Was there a case for inquiry?—Yes, because the four firms of B.I.M. (British Insulin Manufacturers) act in collaboration and because one of them, Burroughs Wellcome & Co., produces more than a third of the insulin supplied in the United Kingdom, thus attracting section 2 of the Monopolies and Restrictive Practices (Inquiry and Control) Act, 1948.

Does this collaboration do harm?—No, the coöperation promotes technical efficiency and has been associated with an increase in insulin yields, improvements in formulation, packing, and presentation, and extensive research.

Is the product satisfactory?—Well, the opinion of a number of authorities is "commendatory almost without qualification."

Is the price too high?—Apparently not. Most insulin is supplied under the National Health Service, so that the retail price is now charged only upon a small proportion of retain sales; but insulin prices in the United Kingdom "are now the lowest in the world with the possible exception of those charged in Scandinavian countries."

What is the import position?—It seems that there have been no commercial imports since the war; the commission suggest that the level of the B.I.M. prices may have made the market unattractive to overseas suppliers.

Do, in the words of the Act, the conditions investigated "operate or may be expected to operate against the public interest"?—If the gland supply arrangements are altered, some change in the present system of allocating pancreas supplies may be desirable, and the Ministry of Health and the purchasing departments should watch prices and profits and exercise supervision if need be. Apart from those two cautionary qualifications, the arrangements made for the supply and distribution of insulin neither operate nor are expected to operate to the public disadvantage.

Those concerned in insulin production have thus escaped the criticisms made in previous reports by the commission, for example those on dental goods where elements of exclusive dealing and collective boycott were brought to notice.

Monopoly is a word of some emotional content; the Left may employ it against Big Business in private enterprise, the Right against nationalised industries. Whatever the political implications of the matter, the report is of general interest. The testimony upon which it is based includes evidence from 16 selected hospitals with diabetic clinics. The survey which section 7 of the Act requires the commission to undertake describes the strength and kinds of insulin and the processes of production. We are given a brief history of the discovery of the drug, its introduction into the United Kingdom, and its supply during the separate periods of 1923–27, 1928–40, and 1941–50. As diabetes mellitus is not a notifiable disease, no exact statistics are available, but the report estimates that there are 200,000 diabetic patients in the United Kingdom and that 60–70% of them receive insulin. Retail chemists distribute 80% and hospitals 20%. There is a short history of the legislation on the subject, mentioning the Therapeutic Substances Act, 1925, and its regulations, the Poisons Rules made under the Pharmacy and Poisons Act, 1933, and the Finance Act, 1934, when Neville Chamberlain freed imported insulin from duty. Naturally, however, the most material finding of the commission is their reassuring declaration that the present arrangements do not operate against the public interest and their refusal to recommend that they be discontinued.

INFLUENZA-VIRUS MUCINASE

In his early descriptions of agglutination of red blood-cells by influenza virus, Hirst[1] divided the reaction into two stages—first, adsorption of virus to red cells and, secondly, elution of virus from the cells. The adsorption appeared to be predominantly physicochemical, but Hirst noted that the elution bore many of the marks of an enzymic reaction. Detailed studies, notably by Burnet and his colleagues in Melbourne, have supported Hirst's original observations; and influenza virus has been found to act in enzymic fashion on soluble inhibitors of virus agglutination.[2] In 1949 Gottschalk and Lind[3] showed that interaction of influenza virus with soluble inhibitor produced a dialysable split product, which Gottschalk[4] later characterised as an N-substituted fructosamine.

Early work on the soluble inhibitors was carried out with materials, such as ovarian-cyst mucoid or ovomucin, which are not always to be had in large enough amounts to satisfy the avid requirements of the biochemist. Tamm and Horsfall[5] showed, however, that human urine contains a potent inhibitor of influenza-virus agglutination; and Gottschalk[6] and Odin[7] have analysed this inhibitor. Gottschalk[6] found that after hydrolysis galactose, mannose, and fucose were present along with a hexosamine base, which on chromatographic evidence seemed to be a mixture of glucosamine and galactosamine. The smallest carbohydrate unit in the mucoprotein was estimated to have a molecular weight of (2500)n, where n is not more than 3 or 4. This carbohydrate unit is regarded as a prosthetic group conjugated to protein; about two hundred such groups attached to each protein molecule make a mucoprotein molecule. In addition to the sugars already mentioned, "sialic acid" was detected in the urinary inhibitor.[7] This monobasic reducing acid, whose structure is still unknown, is found in many inhibitory substances, although in pure form it has no inhibitory activity. "Sialic acid" has similar properties to Gottschalk's[4] split product and is probably an important clue to the chemistry of these inhibitors.

The viruses belonging to the influenza/mumps/Newcastle disease/fowl-plague group, which all show mucinase activity, are the only ones where an intrinsic enzymic reaction has been clearly proved. Yet a mystery remains to trouble the biologist: of what use is this enzyme to the virus? Is it a micro-bulldozer which helps the virus to dig its way through the cell wall? Fazekas de St. Groth[8] cast strong doubt on this possibility when he showed that virus particles were taken into cells under conditions where there was no virus enzymic activity. Does the enzyme help the virus to overcome the effects of the host's normal inhibitors, as some have suggested? This sounds the most attractive hypothesis; but although mucoids inhibit agglutination, they rarely inhibit virus infectivity to any great extent; and the virulence of a virus is unrelated to its enzymic activity. Has the enzyme some intracellular function in virus multiplication; or is it a vestigial organ, a virusiform appendix, which may have had some useful function at an earlier stage in virus evolution? At present the facts allow of little more than idle speculation—a pleasant but often fruitless occupation.

STANDARD FOR SEDIMENTATION-RATE

The British Standards Institution has now turned its attention to tubes for estimating the sedimentation-rate of red blood-cells. This attention is timely since at present the results of different workers are often not comparable. The standard textbooks list up to six methods of estimating sedimentation-rate. The proposed standard adopts only two methods: (1) the Westergren, both normal and a micro modification, and (2) the Wintrobe. This limitation is certainly sensible in this country, where most laboratories use one or the other of these two techniques. The tuberculosis departments and sanatoria tend to rely on the Westergren method, while the clinical laboratories of general hospitals on the whole prefer the Wintrobe method.

The Wintrobe technique was originally designed so that the packed red-cell volume—or hæmatocrit—could be determined on the sample of blood that had first been used for determining the sedimentation-rate; and Wintrobe used the hæmatocrit value to "correct" for anæmia, which increases the sedimentation-rate. Of late years the validity of this correction has been challenged; but the technique remains a useful and simple one. By the original Westergren method the tube had a graduated length of 200 mm. and a bore of about 2·45 mm. Such a tube needs about 1·5 ml. of blood to fill it, which in adults is easily obtained by venepuncture. In children, however, venepuncture may not be convenient or desirable, and the institute's technical committee has therefore recommended in addition a smaller tube of Westergren type. Experiments showed that the bore of the tube must be at least 1·5 mm.; so the committee proposes the adoption of a tube with a graduated length of 100 mm. and a bore of 1·65 ± 0·15 mm., which can be filled with only 0·25 ml. of blood.

The standard specifications seem unexceptionable—except for the micro Westergren tube they correspond to types already in use—and they ensure minimal variation of tube-length, tube-bore, and, in the Westergren tubes, size of the lower orifice. Truly comparable results should therefore be obtained with these tubes.

The committee, recognising the importance of proper stands, propose patterns for the three types of tube. They also give valuable instructions for cleaning the

DICKENS AND THE DOCTORS

FEW real doctors have ever achieved the stature of those concocted by Charles Dickens—though Lord Webb-Johnson, after hearing the Lloyd-Roberts lecture at the Royal Society of Medicine on Oct. 29, tried to make out a case for Lloyd-Roberts himself. The meeting had just had the felicity of hearing Mr. Bernard Darwin on "Dickens's Doctors"; and if they had not known their luck from the start they would have been brought to a proper sense of it by a reminder from Dr. F. M. R. Walshe, F.R.S., the president, that the first three Lloyd-Roberts lectures were on defects of man's structure, racial degeneration, and criminal law and insanity.

Mr. Darwin was somewhat hampered by the richness of his material: we can almost fancy the vast company of doctors on the Dickensian Medical Register a-cocking their medical eyes in an attempt to catch his. Dickens knew more about medicine than the average layman, though a trifle weak on spontaneous combustion. He laughed at doctors, but he liked them too; as we may be sure, Mr. Darwin thinks, from the fact that he had no murderers among them—despite the fact that Dr. William Palmer was at the height of his poisoning practice at about the time he was writing. Many of his doctors are anonymous; and some are spurious, like Doctor Marigold (who was christened after the physician who produced him), or unqualified, like Mr. Alfred Jingle (who asserted that he had saved the life of a female, who had taken prussic acid, by means of a stomach-pump which he happened to have in his portmanteau); and one was a marionette who had trouble with his wires, and delivered his opinions into the air. But among the regular practitioners Dickens had a splendid range, from Sir Tumley Snuffin and Sir Parker Peps (the only two doctors he ever knighted), to poor Mr. Chillip who preferred darkness and draughts to the formidable company of Miss Trotwood, when David Copperfield was on the way. That dull dog Allan Woodcourt in *Bleak House* reminded Mr. Darwin of a don whom he had once asked for an opinion of a dead colleague: "He replied with incredible venom, 'Oh you couldn't possibly *dislike* him.'" Then there was that splendid humbug Mr. Jobling, M.R.C.S., who examined patients for the Anglo-Bengalee Insurance Company, and had a way of smacking his lips and saying "Ah!" Dr. Manette in *A Tale of Two Cities*, with his compulsive reversions to shoemaking, is perhaps more interesting as a patient than as a doctor; and the doctor in Sam Weller's story of the patient who died on principle is mainly notable, Mr. Darwin thinks, for his courageous readiness to admit he did not know how many crumpets would prove fatal. But the doctors whose company he particularly favours are Bob Sawyer of Guy's and Jack Hopkins (who told the story of the rattling fine child who swallowed the necklace) of Barts. Dickens was so fertile, and so uncertain whether he had written enough words to fill an instalment, that he often threw off a new character just to stop a gap. Perhaps Bob Sawyer arrived in this way—certainly Sam Weller's laconic announcement "There's a couple of sawbones downstairs" does not prepare us for this "great creature" (as Chesterton described him). Some find Mr. Sawyer noisy and vulgar, but Mr. Darwin defended him as though he were a favourite younger brother. He smoked in the street: but today who does not? He drank too much: and so did Mr. Pickwick. He called waiters by their Christian names: but Mr. Darwin knew of respectable institutions where distinguished members of our profession call waitresses by their Christian names. Perhaps his habit of sending his boy round to leave bottles of medicine at the wrong houses, and of getting himself called out of church as though to an urgent case, might be regarded as infamous conduct in a professional respect; but then he was so ready to be helpful—to bleed all and sundry on the slightest pretext—and so sound on the curative properties of hot punch. Much must be forgiven Bob, and Dickens clearly forgave him, for he left him—however unbelievably—trying the effects of a little abstinence. Parting wistfully from his noble and but half-explored theme Mr. Darwin exhorted readers of Dickens in the words of Mr. Toots to his wife: "Do, do endeavour to remember the medical man. If you can't, it's of no consequence . . ."

BAROTRAUMA

BAROTRAUMA is by no means a new condition, but its importance increases as more and more people fly in civil and military aircraft. The ears, paranasal sinuses and teeth can all be affected by changes of pressure; and the three types of barotrauma are described by Box[1] in a recent paper.

Otitic barotrauma is a condition in which the ear is damaged when a difference in pressure exists between the middle ear and the surrounding atmosphere. It occurs in aircraft or in caissons, usually when the atmospheric pressure rises during descent, for the normal eustachian tube opens spontaneously during ascent, but not during descent. The tensor muscles of the palate must contract to allow air to enter the tympanic cavity, and this can be done by swallowing, yawning, or auto-inflation by Valsalva's method; but there comes a point at which the pressure difference is so great that the compressible portion of the tube becomes squeezed by the external pressure, and when muscular action is no longer capable of opening it. One or both ears may be affected, and the symptoms produced are pain (which may be very severe), deafness (usually conductive in type), tinnitus (sometimes of alarming intensity) and occasionally vertigo. The changes in the tympanic membrane vary from a slight indrawing, through a stage of congestion and interstitial hæmorrhage, to actual rupture. Effusions of clear fluid or blood into the middle ear may give the appearance of bubbles or of a blue bulging drumhead. The ear may be damaged in this way if the tube fails to open because the passenger does not know what to do, because he is asleep, or because of congestion in his upper respiratory tract. Other causes are hypertrophy of the lymphoid tissue in the tube and malocclusion of the teeth. Ideally flying should be avoided during a severe upper respiratory infection. Treatment of the established condition consists of introducing air into the middle ear either through the eustachian tube or the tympanic membrane. Box mentions only the first of these, and states that politzerisation or catheterisation may be required; but Bateman[2] recommends simple paracentesis of the drumhead as a better method. It can be performed without an anæsthetic and affords immediate relief of pain. The small incision heals very rapidly, and is rarely, if ever, followed by secondary infection of the middle ear. Recurrent attacks of otitic barotrauma may be due to hypertrophy of the lymphoid tissue of the tube. Irradiation, applied either by external or local means, has been used in such cases, but the results are equivocal and the method is not generally accepted.

The pain of sinus barotrauma is also more pronounced during descent, and nasal congestion may lead to the "vacuum" type of headache caused by a blocked ostium. Dental barotrauma, on the other hand, usually occurs during ascent. Molars are particularly affected, and the pain is felt most often in recently filled teeth.

Public Health

TUBERCULIN SENSITIVITY OF CHILDREN IN THE EAST END OF LONDON

H. M. T. COLES
M.D. Lond., M.R.C.P., D.C.H.
REGISTRAR, WESTMINSTER CHILDREN'S HOSPITAL; LATE HOUSE-PHYSICIAN, QUEEN ELIZABETH HOSPITAL FOR CHILDREN, HACKNEY ROAD, LONDON

THIS paper reports the results of Mantoux tests done on 579 children at the Queen Elizabeth Hospital for Children between November, 1950, and November, 1951. It also gives the results obtained in 262 of these children on whom concurrent tests were performed with tuberculin jelly (1) in the ordinary way and (2) on flourpapered skin. The 579 children were either inpatients or attending the outpatient or casualty departments of the hospital, and the vast majority of them were not suspected of, or receiving treatment for, tuberculosis.

METHOD OF MANTOUX TEST

To ensure uniformity all the tests were made and read by the same observer. Each child received an initial injection of 0·1 ml. of 1 : 10,000 Old Tuberculin into the skin of the flexor aspect of the left forearm and an equal volume of control material in the right forearm. Subsequent injections of equal volumes of 1 : 1000 and 1 : 100 Old Tuberculin were given if there was no reaction in the preceding injection. All the results were read 72–96 hours after the injection, the criteria for a positive result being the appearance of an area of erythema or erythematous infiltration at the injection site whose greatest diameter equalled or exceeded 5 mm. in the absence of similar change in the control area. Separate syringes were used for each strength of Old Tuberculin and for the control, a clean needle being used for each injection.

METHOD OF PERCUTANEOUS TESTING

The interscapular area was first cleaned with acetone, and a strip of skin to the right of the midline was gently stroked five times with flourpaper (this was cut into convenient strips 1 in. wide by $1^1/_2$ in. long, a fresh piece being used for each child). Allen & Hanburys' 60% tuberculin jelly was applied to an oval area on each side of the midline and control jelly to similar areas below. The jellies were covered with adhesive plaster for 48 hours, instructions being given for the plasters to be kept dry during this period. The results were read 72–96 hours after the test, a positive result being inferred from the appearance of five or more vesicles or papules within the site of application of the jelly, provided there was no similar change in the control-jelly area. A note was also taken of the presence or absence of erythema.

TABLE I—RESULTS OF MANTOUX TESTS ON 579 CHILDREN

Age (yr.)	Clinically tuberculous				Clinically non-tuberculous					
	Home contact		No contact		Home contact				No contact	
	Open				Open		Closed

RESULTS OF MANTOUX TESTS

A questionnaire was completed for all the children tested. This contained clinical, family, and social details as well as a classification of the child as regards active tuberculosis, presence or absence of home contact with tuberculosis, and the results of intradermal and percutaneous tests. An analysis of these results is presented in table I. 579 children were Mantoux-tested, of whom 57 were Mantoux-positive.

DISCUSSION

An accurate assessment of the value of the tuberculin reaction in the diagnosis of tuberculous infection in any age-group depends directly on a knowledge of the percentage of positive reactors among clinically non-tuberculous persons in that age-group. D'Arcy Hart (1932) has pointed out that it is also important for the number of home contacts in the series not to be unduly high. Since the number of home contacts in any collection of children is necessarily fortuitous, it seems to be important, in assessing the diagnostic value of the tuberculin reaction, to exclude them along with all cases of proven tuberculosis.

TABLE II—PERCENTAGES OF MANTOUX-POSITIVE AND CLINICALLY NON-TUBERCULOUS CHILDREN WITHOUT HOME CONTACT IN 1929, 1931, AND 1950–51

Survey	Age-group (yr.)			
	0–2	2–5	5–10	10–15
1929 (Hart 1932)	4·5	15	27	59
1931 (Dow and Lloyd 1932)	13·6		31·2	54·4
1950–51 (present report) ..	4·94		9	18

All children with proven tuberculosis gave positive Mantoux reactions. Of the clinically non-tuberculous children 37·5% of those with open home contact, and none of those with closed home contact, gave positive Mantoux reactions. 7·68% of clinically non-tuberculous children without home contact were Mantoux-positive. None of the infants aged less than 1 year were Mantoux-positive.

The last published series of Mantoux tests on London children were made in 1929 (Hart 1932) and 1931 (Dow and Lloyd 1932). In the last twenty years a great many factors may have conspired to modify the incidence of tuberculous infection in London children, and most authorities suggest that it has fallen. Table II shows clearly that the percentage incidence of Mantoux positivity is in fact very much less in 1950–51 than in 1929 and 1931.

In very general terms the percentage incidence of Mantoux-positive children in each age-group in 1950–51 was about a third of those in 1929 and 1931. Roughly speaking, one in every twenty between 0 and 5 years is Mantoux-positive, one in every ten between 5 and 10, and one in every five between 10 and 15. These results seem to indicate that the determination of tuberculin reactivity is a useful diagnostic measure even up to the age of 15. However, the number of children over 10 who were tested was relatively so small (only 50) that much weight should not be placed on the percentage figures for this group.

TABLE III—MANTOUX REACTIONS IN CHILDREN GROUPED ACCORDING TO NUMBER OF ROOMS OCCUPIED PER HEAD IN FAMILY

No. of rooms per head	Mantoux-positive	Mantoux-negative
Up to $^1/_4$ ..	3 (*5·5%*)	16 (*3·2%*)
$^1/_4$–$^1/_2$ ..	5 (*9·1%*)	66 (*12·7%*)
$^1/_2$–$^3/_4$ ..	24 (*43·6%*)	167 (*32·6%*)
$^3/_4$–1 ..	16 (*29·1%*)	162 (*31·7%*)
1–$1^1/_2$ ..	7 (*12·7%*)	75 (*14·7%*)
$1^1/_2$–2 ..	..	22 (*4·3%*)
More than 2 ..	..	4 (*0·8%*)

It was thought possible that the war-time evacuation of children from London might have had an influence in *preventing or in promoting tuberculous infection.* A note was made in the case of all children who were born before Jan. 1, 1945, to say whether or not they had been evacuated. Of 199 such children 63 had been evacuated. Of the 199 children 24 were Mantoux-positive, and 9 of these had been evacuated; 175 were Mantoux-negative, and 54 of these had been evacuated. Hence, of the Mantoux-positive children 37·5%, and of the Mantoux-negative 30·9%, were ex-evacuees. The difference between these two figures is too small to infer that evacuation raised the chances of becoming Mantoux-positive.

More interesting deductions can be made from a consideration of the details of housing and family income in relation to the percentage incidence of tuberculin sensitivity. Table III shows the numbers of Mantoux-positive and Mantoux-negative children grouped according to the number of rooms per head in the family. The percentage figures relate to the total number Mantoux-positive and Mantoux-negative, and these are presented graphically in fig. 1. From the figure and the table 12 children were omitted because they came from institutions or had been in hospital for a long time.

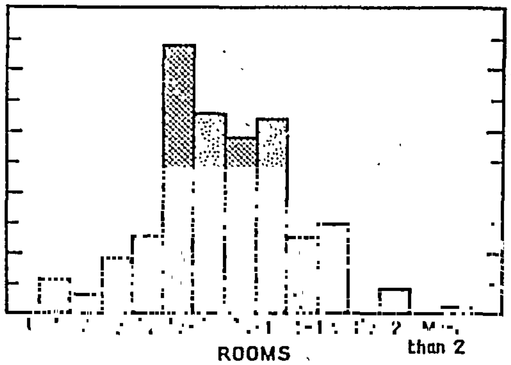

Fig. 1—Percentages of Mantoux-positive and Mantoux-negative children grouped according to number of rooms per head in family: hatched, Mantoux-positive; stippled, Mantoux-negative.

From these figures it will be seen that more than 58% of the Mantoux-positive children came from families with $^3/_4$ of a room per head or less, and none from those with $1^1/_2$ or more rooms per head. About 81% of all the children lived in families with 1 or less room per head, and nearly 50% with $^3/_4$ or less room per head.

Table IV and fig. 2 are similarly arranged to show the influence of the amount of housekeeping money available per head in the family per week. Here the most striking features are the relatively large number of positive reactors from families with less than 10*s.* per head devoted to housekeeping expenses; nearly 30% of positive reactors are from families with up to 20*s.* per head in the family. The figure and the table also show that the bulk of these East End families spend between 15*s.* and 35*s.* per head on food, clothing, and shelte 16 children were omitted: 12 were from institutions o had been in hospital a long time, and for 4 others th details of *housekeeping money were not known.*

RESULTS OF PERCUTANEOUS TESTING

A comparison was made of the ordinary tuberculi jelly test and the flourpaper technique. 262 childre were tested, and results are detailed in tables V and VI.

DISCUSSION

In 1946 Deane described a new way of performin the percutaneous tuberculin-jelly test which he claimed enhanced its reliability. This consisted in gentl stroking of the selected skin area with an abrasive afte preliminary cleansing with acetone. Deane used cabinet-maker's sandpaper no. 0, lightly abrading the skin with five or six gentle strokes before applying the jelly. 40 children, positive to Mantoux 1 : 1000, were tested with the ordinary jelly technique and his modified method. The former gave 35 positive results (87·5% agreement with the Mantoux test) and the modified method gave 40 positive results (100% agreement).

TABLE IV—MANTOUX REACTIONS IN CHILDREN GROUPED ACCORDING TO WEEKLY AMOUNT OF MONEY SPENT ON FOOD, CLOTHING, AND RENT PER HEAD IN FAMILY

Housekeeping money per head per week (*s.*)	Mantoux-positive	Mantoux-negative
Up to 10	4 (*7·3%*)	1 (*0·2%*)
10–15	..	13 (*2·5%*)
15–20	13 (*23·6%*)	85 (*16·7%*)
20–25	6 (*11·0%*)	138 (*27·1%*)
25–30	12 (*21·8%*)	112 (*22·0%*)
30–35	12 (*21·8%*)	89 (*17·5%*)
35–40	5 (*9·0%*)	30 (*6·0%*)
More than 40 ..	3 (*5·5%*)	40 (*8·0%*)

Dick (1950) asserted that sandpaper no. 0 was too coarse, and advocated the use of a finer paper known *in* the trade as cabinet-maker's flourpaper. In his investigations he gave six gentle strokes with the flourpaper after cleansing the skin with acetone. Plaster was applied over the jelly for 48 hours, and the results were read 24–48 hours after its removal. Erythema was ignored, but four or more vesicles at the site of *application* of the jelly were regarded as a positive result. By this technique Dick claimed that, with a jelly of Old Tuberculin 60%, results approximated to those of an intradermal Mantoux test of 1 : 1000.

In a large series of tests on subjects aged 5–20 he found "two apparently false positives by intradermal standards among a total of 224 positive to the modified jelly test—that is, rather less than 0·9%. In a comparative test of the flourpaper method properly executed and grossly over-used there was no evidence of an increased incidence of false positive reactions. Dick also compared the relative efficiency of three jellies: 0·2% P.P.D. jelly (designed approximately to equal the tuberculoprotein content of undiluted O.T.); 60% Old Tuberculin jelly; and 85% Old Tuberculin jelly. The 0·2% P.P.D. jelly was definitely inferior to 60% Old Tuberculin

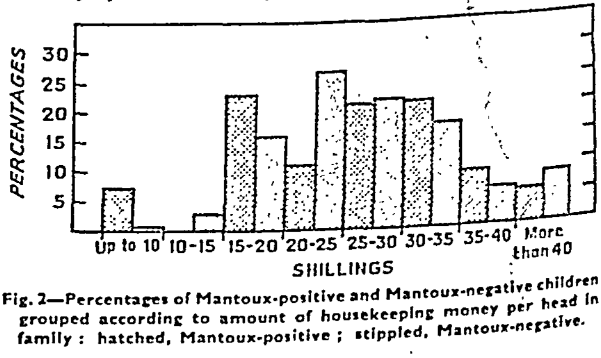

Fig. 2—Percentages of Mantoux-positive and Mantoux-negative children grouped according to amount of housekeeping money per head in family: hatched, Mantoux-positive; stippled, Mantoux-negative.

TABLE V—RESULTS OF MANTOUX AND PERCUTANEOUS TESTS IN 262 CHILDREN

Percutaneous tests	Mantoux-positive (24)			Mantoux-negative 1 : 100 (238)
	1 : 10,000	1 : 1000	1 : 100

Jelly test − Flourpaper +	..	3	2	44
Total	15	4	5	238

jelly, and the 85% Old Tuberculin jelly had no advantage over that of 60%.

Lendrum (1951) reported his results on a large series of Portsmouth children and young adults. He found that Old Tuberculin jelly applied by the flourpaper technique gave 98·4% agreement with 10 tuberculin units (0·1 mg.) of Old Tuberculin intradermally. He also used a 60% P.P.D. jelly but found it to be inferior to Old Tuberculin jelly.

Clark (1951) reported a series of 1499 children who were Mantoux-tested and also had Old Tuberculin jelly applied to skin previously rubbed vigorously with ether. There were identical results in 1440 cases (96·06%).

TABLE VI—RESULTS IN TABLE V DIVIDED INTO AGE-GROUPS

Percutaneous tests	Age-group (yr.)											
	0–5 (137)				5–10 (102)				10–15 (23)			
	Mantoux +			M −	Mantoux +			M −	Mantoux +			M −
	1 : 10,000	1 : 1000	1 : 100		1 : 10,000	1 : 1000	1 : 100		1 : 10,000	1 : 1000	1 : 100

JT − FP +	..	1	1	26	..	2	1	18	..	..	..	..
Total	7	2	1	127	4	2	4	92	4	..	..	19

Tables V and VI show the results obtained in concurrent tests with tuberculin jelly by the ordinary method and with flourpaper, compared with the Mantoux reaction. 262 children aged 0–15 were tested. Of these 24 were Mantoux-positive (9·16%). Congruous results were obtained in 206 (78·62%) and incongruous in 56 (21·37%). These incongruous results, further analysed, show that the jelly test and the flourpaper test both disagreed with the Mantoux test in 6 instances; the jelly test disagreed with the flourpaper test and the Mantoux test in 5 instances; and the flourpaper test disagreed with the jelly test and the Mantoux test in 45 instances.

The ordinary jelly test disagreed with the Mantoux test in 11 cases (4·2%). Of these, 9 jelly tests were negative with positive Mantoux reactions, and 2 jelly tests positive with negative Mantoux reactions.

The flourpaper test disagreed with the Mantoux test in 51 cases (19·5%). Of these, 5 flourpaper tests were negative with positive Mantoux reactions, and 46 (17·5%) were positive with negative Mantoux reactions. In this series the flourpaper test gave 23 times as many false positive readings as did the ordinary jelly test, and missed giving a reaction in 5 cases as opposed to 9 cases with the jelly test. These 5 misses represent an error of 1·9% of the total.

Table VI shows the results in three 5-year age-groups.

In 137 children aged 0–5 years tested there were 108 congruous results and 29 incongruous results (21·17% disagreement). Of these children 7·3% were Mantoux-positive; 5·1% had positive ordinary jelly tests; and 25·5% had positive flourpaper tests. The 102 children aged 5–10 years gave 78 congruous and 24 incongruous results (23·5% disagreement). Of these children 9·8% were Mantoux-positive; 3·04% had positive jelly tests; and 24·5% had positive flourpaper tests. The 23 children aged 10–15 gave 20 congruous and 3 incongruous results (13·04% disagreement); 17·4% were Mantoux-positive; 26·1% were jelly-positive; 21·7% were flourpaper-positive.

These results do not suggest that false positive reactions are much commoner in infants and young children under 5 with the flourpaper technique than in older children. In all infants under 1 there were no reactions with intradermal or percutaneous tests. In the age-group 0–5 there were 26 false positives with the flourpaper test (19%) against 18 aged 5–10 years (17·6%).

The flourpaper tuberculin-jelly test seems to be superior to the ordinary tuberculin-jelly test as an indicator of tuberculin insensitivity, but is apt to give rise to a high percentage of false positive reactions; hence positive results require checking by intradermal tests. Possibly the aberrant reactions with tuberculin jelly applied to the flourpapered skin are due to one or more of the proteins other than tuberculoprotein present in Old Tuberculin.

SUMMARY

The results are presented of a Mantoux survey of 579 children from the East End of London.

None of the infants aged less than 1 year were Mantoux-positive. 547 children were clinically without tuberculous infection and gave no history of home contact. Of these, 42 were Mantoux-positive (7·68%). The incidence of these children in three 5-year age-groups was:

0– 5 years	.. ..	4·94%
5–10 years	.. ..	9%
10–15 years	.. ..	18%

These percentages are roughly a third of those for comparable groups reported by D'Arcy Hart (1932) and Dow and Lloyd (1932). Broadly speaking, one in every twenty aged less than 5 years, one in every ten aged 5–10, and one in every five aged 10–15 is Mantoux-positive.

More Mantoux-positive children came from families with the smallest amount of living space in the home, and from families with the smallest incomes.

Comparative surveys of the ordinary tuberculin-jelly test and the flourpaper technique with intradermal control are reported. 262 children were tested. The ordinary jelly test disagreed with the Mantoux test in 11 cases (4·2%), of which 2 were false positives. The flourpaper jelly test disagreed with the Mantoux test in 51 cases (19·5%), of which 46 were false positives.

I wish to thank the research committee of the Queen Elizabeth Hospital for Children for permission to make these tests; the physicians and surgeons of the hospital for allowing me to make them on their patients; and Dr. H. M. M. Mackay and Dr. R. H. Dobbs for their encouragement and advice.

Lead Poisoning from Nursery Cot

An 11-month-old boy, whose death from lead poisoning was the subject of an inquest at Maesteg,[1] was poisoned when he chewed the paint off his cot. The cot was originally painted by the manufacturers with a harmless paint, but a lead-containing paint was used by the parents to redecorate it. A recent article in our columns[2] pointed out that lead paint in the nursery is the commonest cause of lead poisoning in children in this country.

Training in Mothercraft

The London County Council have decided that the rehabilitation of mothers whose "home circumstances and ill health are such that they have no control over their children and little understanding of how to bring up the family" may reasonably be considered to be included in the duties assigned to local authorities by the National Health Service Act, 1946. As an experiment the council therefore propose next year to provide training in mothercraft for ten women during 1952–53. The health visitors of the council will continue to help many of these women in their own homes, but where this is not possible the council plan to send expectant or nursing mothers and mothers with children below school age to recuperative centres for training and reablement. The children may, where suitable, accompany their mothers to the centre.

THE CHILD UNDER THE N.H.S.

Discussion by Medical Women's Federation

ONE of the main events of the Medical Women's Federation meeting in London last Saturday was a discussion on The Care of the Child in the National Health Service. Dr. DORIS ODLUM, president of the federation, presided. The chief arguments put before the large audience were (1) that responsibility for the child's medical care is now divided among too many distinct clinics and individuals; (2) that the general practitioner must be given a larger share of the work and become a true family doctor; and (3) that the rivalry between doctors and health visitors, which exists in some regions, must end. The evils were thought to be largely those of inadequate exchange of information and lack of the right education.

Dr. URSULA SHELLEY (London) opened by pointing out that the infant-mortality rate had dropped from 153 in 1900 to 30 in 1950, while such diseases as diphtheria and rickets had almost vanished. This was the fruit of a whole series of measures such as the start of school medical inspections in 1908 and the Maternal and Child Welfare Act of 1918, and the present very high standard of child health in this country was not the work of the N.H.S., though the provision of free medical attention and free hospital treatment for all since 1948 was undoubtedly a valuable additional measure.

The trouble now was not too little medical attention, but too much—of a fragmentary kind. The child was born in hospital; after ten days he went home with his mother, and the health visitor called to see him: later he attended the infant-welfare clinic, which might refer him direct to hospital if he were ill. Alternatively he might be seen for the first time by the family doctor, but in a little while he would come within the purview of the school medical officer, who might refer him to the nutrition clinic, the enuretic clinic, or a whole host of others. When finally he emerged from his school-days he came back to the general practitioner, without a written word of his medical history in spite of all the records which had been compiled by the different services. Mostly each clinic tended to keep its discoveries to itself, and each saw only a part of the child. But the child was not an isolated unit but a member of a family. An uncle's tuberculosis, a father's nasal trouble, a mother's insufficient love, and poverty and overcrowding in the home were all important factors in his existence. The one person who was fitted to know all these factors and assess them, and to follow continuously the child's medical history, was the family doctor. He must be given more opportunity to do work now performed by local-authority clinics. He should do all the immunising and vaccinating of his patients—which should be made compulsory again. He should visit his child patients in hospital and interpret to the parents the hospital specialist's advice. In London a child referred by the school medical officer to the psychiatric clinic might have to wait six months for a diagnostic interview, when a family doctor who knew the full home background could have settled the problem almost at once. Child pyschiatry was a field the general practitioner ought to enter, but he often suffered from lack of confidence or knowledge. He needed refresher courses in pædiatrics, and contact with specialist clinics to guide him, as well as health centres to ensure that he could get an X-ray and laboratory service directly. The training of the medical student needed to be more practical, with less emphasis on rare diseases and special treatments and more about the various clinics and auxiliary workers who existed in the world of practice. There should be some financial inducement to the practitioner to undertake a greater share of child-health work, because it had to be recognised that a child gave much more work than an adult. A man with a family of his own to support could not be expected to occupy his time with this extra work when the capitation fee was the same for child and adult.

Dr. Shelley also pointed out that there was a lack of sufficient long-stay accommodation for children, for instance for those with tuberculosis, physical handicap, or mental defect. This sometimes blocked beds in acute hospitals. It also meant the children were not getting the special rehabilitation they should.

Dr. CHARLOTTE NAISH (York) described how she was dissatisfied with the division of medical responsibility even before the N.H.S., and in 1942 she set aside a surgery afternoon to run her own independent infant-welfare clinic. Although she charged fees for attendance, the mothers came because they preferred the continuity of care by one person, and appreciated the opportunity to have their postnatal examination at the time they brought their children for weighing. She organised a mothers' club and a fathers' club in conjunction with her welfare clinic and found she could thus do very valuable educative work, creating a closer relationship with patients, and also reducing the number of night calls by allaying fears. Since 1950 the local authority had allowed her the services free of a health visitor paid from the rates, which showed how there could be fruitful coöperation between practitioner and public-health worker. Though a practitioner might not know much about preventive medicine he could quickly pick it up. Running his own clinic need not be time-consuming, and the education thus given could help parents to nurse their children at home and so reduce hospital admissions. The home help could do the shopping, and the district nurse might tender useful advice, but only the mother could nurse the child.

Dr. Elspeth Warwick (Nottingham) defended the maternity and child-welfare and school medical services against some of their critics. The work these services did was laid down by law, and some of the comments arose from lack of detailed knowledge of their capabilities and functions. Since 1948 local-authority antenatal clinics had been used less, and more practitioners were giving their patients antenatal advice. This was a pity since the health and mothercraft teaching at the local-authority clinic was a very valuable part of its work, and it was useful for the mother to get to know her health visitor before her baby was born. A way must be found of merging the work of practitioner and local-authority clinic, either by inviting the doctor to see his patients at the clinic premises or by providing him with a local-authority midwife and health visitor. Local authorities ought to invite doctors to periodic conferences, and doctors ought to feel they must attend. Special efforts should be made to bring doctors and health visitors to know one another personally.

Dr. Sylvia Guthrie (Manchester) put in a plea for the maintenance of the special children's hospitals, both because of the special needs of children—for instance in schooling and physiotherapy—and because the sick children's nurse was much better trained there than in the small children's ward of a general hospital. She thought hospitals should invite health visitors on ward rounds, and bring together general practitioner, clinic worker, and specialist in discussion groups.

Dr. Margaret Reed (Cambridge) said she had run an infant-welfare surgery for fifteen years. She felt there was some danger of doctor and health visitor being rivals in the care of the child. As medical officer to the Perse School for Girls she always referred girls to their own doctor. Some of the commonest troubles, however, were postural and could be treated by the physical training mistress. More should be done for the children of problem families, and more provision made for mentally handicapped children.

Dr. Catherine Crane (M.O.H., York) thought the extent to which coöperation between the different parts of the health service already took place had been rather minimised. Many local-authority health committees had coöpted general practitioners, and medical officers of health were on local medical committees. Midwives, district nurses, tuberculosis visitors, and so on, all got on well with practitioners. It was only the health visitor who was shunned, though one practitioner in eight in her area holds regular discussions with a health visitor. But only Dr. Naish had wanted a health visitor at her clinic.

Dr. Margeret Methven (Edinburgh) thought that prevention and early treatment of behaviour problems and neurosis should be the family doctor's province, but he needed more knowledge of the subject, as did the health visitor, while hospital obstetric services ought to be more practically aware of the importance of the mother-child relationship.

In further discussion Dr. Dorothy Taylor (Ministry of Health) said the Ministry had been worried by the opposition to health visitors. They were qualified nurses, who could help with feeding difficulties and the ailing child where lengthy guidance and supervision of the mother was needed. Dr. Mary Crosse (Birmingham) also emphasised their value in educating mothers, and thus doing preventive work. Dr. Audrey Gardham (London) wanted the school medical officer to send a summary of the school-leaver's health record to his family doctor. Dr. Annis Gillie (London) pointed out that many general practitioners did part-time clinic work, which was valuable experience and gave them a foot in both camps.

Dr. Georgie Brodie (lately Ministry of Health) summed up the conference, and praised the work being done at York under a woman medical officer of health. Interchange of information was lacking between one branch of the N.H.S. and another; there was ignorance among the members of the health team of each other's responsibilities and work, and ways must be found of improving this situation. All the same, Britain was the Mecca of the world's child-health workers.

THE JOHN RYLE HEALTH CENTRE

An Experiment at Nottingham

The new health centre at Clifton, Nottingham, was opened by Miss Enid Russell-Smith, an under-secretary of the Ministry of Health, on Oct. 17. The centre has been named after the late John Ryle, first professor of social medicine in the University of Oxford.

The centre is a block of four terraced houses (fig. 1) which were modified during building by providing through communication between all the houses on the ground floor and between two houses on the upper floor. The ground floor is taken up by 4 general practitioners' surgeries, and the upper floor by a small maternity and child-health centre, and two self-contained flats for a resident nurse-secretary and a caretaker. The centre will serve a housing estate which has been going up for the past year. The population at the moment is only 2000, but there will be 22,000–23,000 people living there when the work is finished in four years' time.

The circumstances seem particularly favourable for the successful development of a health centre. The estate is entirely new, it lies about five miles from the centre of Nottingham, and it is separated from the city by a green belt more than a mile wide. The only other dwellings within a mile or so are in a hamlet of about 50 houses, and the nearest existing medical services are two miles away.

The plans in figs. 2 and 3 show the way in which the accommodation is set out.

Ground Floor

Each surgery occupies the ground floor of one house, and has a separate entrance. The surgery has been planned to allow a rapid circulation of patients. The front door opens into a small hall, leading to a waiting-room which comfortably accommodates 15 people. The waiting-room leads in turn to a consulting-room which is the living-room of the ordinary house, the only extra fixture being a washbasin. The examination-room, which would have been the kitchen, is little smaller than the consulting-room, and contains a couch and facilities for sterilisation and urine-testing. A door leads from the examination-room back to the hall.

Communicating doors for the doctors lead from waiting-room to waiting-room. The central "tunnel" which normally goes through to the back of the terrace has been bricked up, and its floor made level with that of the two adjacent rooms. Besides providing a connection between the middle two surgeries, the "tunnel" also acts as a store.

Space and water heating throughout the building is by electricity.

There is a small external store for each house. These are used in various ways—e.g., one store contains an electric incinerator.

The forecourt of the building is paved, and at the back there is a paved area for the parking of cars and prams.

Upper Floor

The accommodation in the local-health-authority centre is small, but it provides useful temporary facilities for the

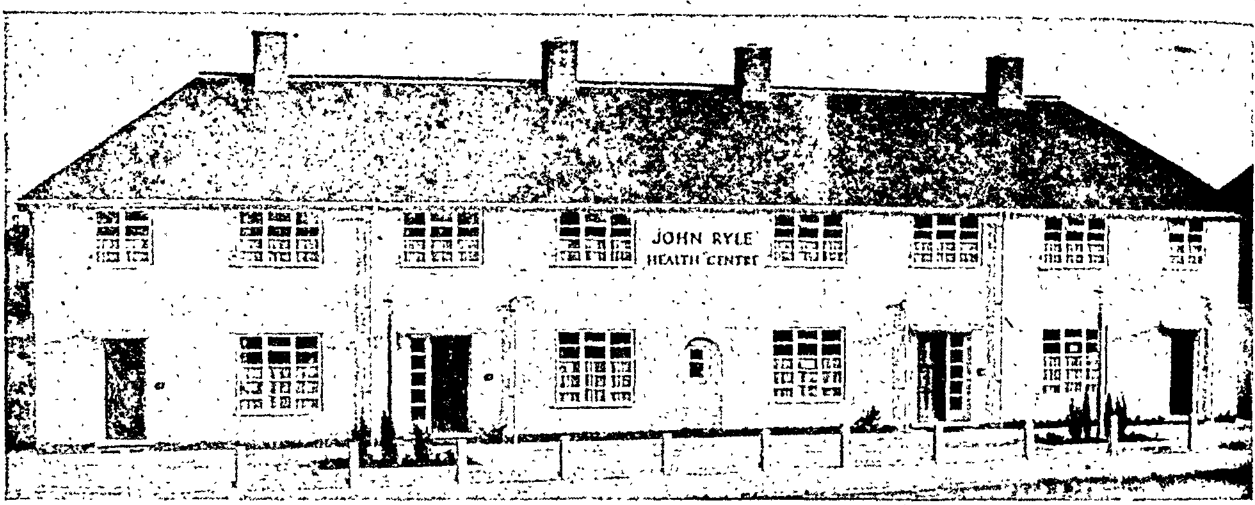

Fig. 1—The John Ryle health centre.

care of mothers and children among the population at the moment, and it will probably cater for a population of about double the present figure.

The two flats for the nurse-secretary and caretaker are reached through the halls of two of the surgeries. Each flat contains a living-room, a bedroom, a kitchen, and a bathroom.

Working Arrangements and Administration

The doctors who use the centre belong to four firms, each having its own surgery, and they began work in the surgeries on Oct. 20.

Records will be kept by the individual doctors. The telephone in each surgery is linked with a switchboard in the office of the centre, which will be staffed between the hours of 9 A.M. and 5.30 P.M. At other times the telephone extensions will be put through to the individual doctors' consulting-rooms or, on rota, to the flat of the caretaker or the nurse-secretary.

An agreement on the lines of the model contract prepared by the British Medical Association, the Ministry of Health, and the London County Council has been completed between the City of Nottingham Corporation and the Nottingham County and City Executive Council, while a suitable agreement of a similar kind has been concluded between the individual firms of doctors and the executive council.

The rental to be paid under these arrangements includes accommodation, telephone facilities, and lighting and heating, but not secretarial and nursing assistance. However, a home nurse lives in a nearby house, and will be able to carry out duties in the doctors' surgeries which she would normally do in the home—a policy already adopted elsewhere in the city.

This kind of centre differs in many ways from those already in use in other parts of the country.[1] The surgeries are entirely separate and self-contained units, and will not be used for any other purpose. The records will not be kept in a central office.

The type of building and accommodation is not very different from that to which most patients are now accustomed. The small suites, including the separate examination-room, provide adequate facilities for all the work of general practice.

In England Now

A Running Commentary by Peripatetic Correspondents

HERE in the Falkland Islands we lead a country life—even in the Colony's capital, Port Stanley, which has about 1100 inhabitants. The main occupation is keeping sheep, of which there are some 650,000. The climate requires them to be hardy, with thick fleeces; and they are bred for wool, not for mutton. In former years sealing played a big part in the island life; but what remains of it is now confined to the West Falkland, where a limited number of sea-lions are killed annually; and in the Colony's coat-of-arms the seal has been replaced by a sheep. The old device, however, remains the same: *Desire the Right!* This sounds very well, but its meaning is not so plain as one would think. Only the other day I came across a pamphlet (commemorating the Colony's centenary in 1933) which explains that "desire" derives from the ship *Desire* in which John Davis discovered the Falklands in 1592, and "right" stands for the Right Whale, a now rare whalebone species which was in the old days plentiful and important for the Falklands.

In other parts of the Southern Hemisphere sheep-farming is impaired by heat-waves, sandstorms, and droughts; but here a long cold spring, with snow showers and blizzards, brings danger to lambing. According to the meteorological records, we have the same amount of annual sunshine as Kew Gardens; but we find it hard to agree with these statistics, for we have to burn a peat fire throughout the year. Living in the Antipodes means, of course, that the sunny side of a house faces north, that the waxing moon here is the waning moon at home, and that I get my hay-fever in January. At the end of one's life one goes "h' East" in the Falklands instead of "going West," as in England.

I found it difficult at first to follow the peculiarity of pronunciation which the "Kelpers" (i.e., Falklanders, from kelp, a seaweed) share with the Cockneys. I know now, of course, what a "hitching heczema" means; yet the other day I felt flabbergasted. One of our workmen at the hospital asked me about his "hydrops." What an educated chap, I thought, and was about to indulge in a lengthy and suitable explanation of this unpleasant condition, when the local sister came to my linguistic rescue.

* * *

A murrain on your metric system and a plague on all these infuriating international units. Why can't we prescribers emulate the electrophysicists with their amperes, volts, and watts? How satisfying to be able to order a hench of cortisone or a kendall of compound F! How stimulating to remember that with insulin one banting equals two bests, and how absolutely right that the adult dose of penicillin should be a whole fleming! But I see one snag. Difficulties might arise if we were asked to prescribe an armour of A.C.T.H., a squibb of isonicotinyl hydrazine, or a pfizer of terramycin.

* * *

"It's turned out quite a nice day!"

"Yes; they were wrong about it on the wireless—they said it was going to rain!"

The second woman's voice was quite aggrieved, as though the B.B.C. had done her a personal injury. Perhaps we are getting to rely too much on weather forecasts: it is seldom nowadays that I hear anyone declare forthrightly that he thinks it looks like rain, or snow, without immediately backing up his opinion by quoting the five-to-eight forecast or, worse still, apologising for having missed it. Just as the amateur musician has been discouraged by the perfection of broadcast performances, so we tend to give up faith in our amateur status as weather-forecasters, and lack the robust self-confidence that shepherds and farmers expressed in proverbial weather lore. Or is it another symptom of our dependence on the Welfare State that we expect protection even from the misfortune of being caught out without our mac?

* * *

Replete with whither articles, may I add one more to the series—"Whither Whither Articles?" It strictly adheres to the formalised style of mellow consideration of the past, general distrust of the present, and fiendish hope for the future characteristic of this genre.

Of proud heritage, these contributions are thought to spring from an unsigned parchment discovered at Cos "Whither Higher Qualifications?" The first definitive article, however, is, without doubt, "Ye Cruele Wynd—Whither doth it go?" (Sir Trumpet Agonie). This aroused the interest of the profession and in quick succession came "Whither Simples?" "Whither Ye Ravenous Leech?" "Whither Flies in Winter?" and "Whither Ye Drastick Purge?" Here the Soviet claim to originality may safely be discarded. Of later contributions "Whither Body-snatching?" (Burke et al.) may be noted.

In the twentieth century medicine moved so rapidly that there was no time to write, or even bother, whither things were going, and attention was only drawn to the neglected branch of medical literature by the outstanding "Whither the Descending Pile?" (Disgustis 1920). This reversed the trend, and henceforth, as a new concept was mooted, quickly in its wake appeared a whither article. A few landmarks may be quoted: "Whither Bloodletting?" (Hirudon 1920); "Whither Sex?" (Haffkrank 1930); "Whither Patients?" (Consultant 1948); "Whither Me?" (Registrar 1952). This technique, it must be admitted, left the field somewhat over-investigated, but out of this seeming danger the modern approach was evolved—viz., "Whither the Public Health?" "Whither Social Health?" "Whither the Nation's Health?" "Whither Community Health?" "Whither the People's Health?" "Whither Group Health?" "Whither State Health?" "Whither Health?"

Such new conceptions leave us, who have the welfare of whither articles at heart, looking confidently to the future. With the Minister's coöperation, and an indulgent Treasury, and as the gap between practitioner and specialist of whither articles closes, we envisage a bright new scene where community medical centres are busily, yet happily, engaged in the production of more, better, brighter, and more literate whither articles. The recent decision to give us trainee whither-article writers and the promise of a future College of Whither-Article Writing cannot fail to have the support and enthusiasm of us all. Proudly then can we, the practitioners of this difficult branch of medical art, say "Whither Do We Go From Here?"

* * *

Whenever I go out with a shotgun I am astonished how seldom the birds fly into my pattern; it seems that they bear a charmed life. Or at least so I thought till I spent an hour at a shooting school, which I can thoroughly recommend as a salutary, if expensive and humiliating, experience. You would think that you could hardly miss those footling little flying saucers lobbed out of a trap, but when you have failed at the first five bobs' worth it pays to listen to your instructor. According to mine the fact that I ever hit anything at all is little short of miraculous, for not only is my weight distributed wrongly but the wrong eye is in control. Further the venerable 12-bore which I have been using these thirty years doesn't fit and casts off to the left. However, all these things are now in process of being put right and next season it will be, I gather, virtually impossible for me to miss anything. In this unlikely event I shall, of course, give up shooting at once as anybody would, but somehow . . .

The practical psychiatrist—have we found him? The closing paragraph of a letter of application for a clerical vacancy in our hospital makes us think we have him on our staff!

> "I would like to tell you that I have been away from work owing to my nerve trouble, and at the moment I am seeing Dr. B—— in your Psychiatric Clinic, and he suggests I will be much better at work. Anticipating a favourable reply,
>
> Yours . . ."

Letters to the Editor

DENTAL TREATMENT OF CHILDREN

SIR,—In your leading article of Oct. 25 you describe the employment of ancillary workers for the dental treatment of children as an "unexceptionable development." But the evidence in favour of the *immediate* introduction of these ancillaries is hardly as conclusive as you suggest.

The abuse and quackery which flourished before the Act of 1921, after which all entrants to the profession had to obtain a qualification and be registered, have not unnaturally caused some concern as to the possible later results of the introduction of ancillary workers without degrees within the profession. Given adequate safeguards, many members of the profession are in favour of the introduction of these workers, since many routine procedures can be carried out by them under the direction of qualified practitioners, thus freeing the latter for more highly skilled or specialised work. The crux, however, is whether this is the right *time* for their introduction.

Much attention has recently been drawn to the fact that the school dental service is insufficiently staffed and that conservative treatment to preserve children's teeth is quite inadequate. This is unfortunately true; but the emotional aspect of helping the children should not be allowed to distract attention from the wider problem of providing an adequate dental service for all ages. The need for fillings to preserve the teeth may be just as important (or more important) at, say, 18 than at 12, and it is of little value to shift the emphasis from one section of the community to another if the main trouble is that there are far too few dental surgeons.

It is perhaps not generally appreciated that in this country there is one dentist to 4400 of the population, compared with approximately 2600 in New Zealand and 1730 in the United States. That this deplorably low ratio is likely to fall still further in the near future was forecast in the Teviot report 1946. Are we then to recruit and train more dental surgeons, or to fill the thinning ranks with ancillary workers capable of carrying out only limited sections of treatment?

There is one encouraging factor in an otherwise gloomy situation—the very large numbers of students at present applying for entry to the dental schools. But—and here comes the difficulty—these schools are already full to overflowing, and a high proportion of potential dental surgeons has to be turned away to be lost to the profession owing to lack of training facilities. It has been argued that with the shorter course given to ancillary workers more could be trained in the time and the cost to the country would be less. A factual and objective analysis in the *British Dental Journal* of Jan. 1, 1952, has produced, however, some disturbing information on these points. It is shown that the cost of educating an ancillary dental worker in New Zealand in a State school with only a 50% ratio of professional to non-professional teaching staff was only 19% less than the cost of production of a fully trained dental surgeon in the university dental schools. The article points out in addition that the Fulton report from New Zealand shows that of every 100 school dental nurses trained to do fillings 30 will have resigned in five years and 83 in twelve years. The accommodation for training dental surgeons in this country is already inadequate and overtaxed, yet it is this same accommodation which would have to be used for the training of ancillary workers. We should be forced therefore to reduce the output of qualified dental surgeons still further in order to train workers who in the end could only carry out limited forms of treatment.

It is clearly essential that the evidence should be most carefully examined and further statistical information obtained before the country is committed to this form of ancillary worker who appears to cost so much to produce and shows such a high rate of wastage in addition to diminishing still further the number of qualified dental surgeons that can be trained.

As I have said, there is a very real danger that the feeling that adequate treatment must at all costs be provided for children may mask the underlying facts of the situation. It is clearly of little value to provide an adequate service for children up to the age of 16 and then deny this service at a later age. In New Zealand, where dental ancillaries have been employed for thirty years 12% of army recruits examined at the age of 18 years in 1950 needed to have all their teeth removed. It is self-evident that the provision of a school dental service is not the answer to the problem. The suggested form of school dental service employing ancillary workers is, however, itself open to criticism. It is postulated that children's dentistry is simple routine and that workers trained for only half the time of a dental surgeon are quite adequate to fill children's teeth. Yet the fillings in permanent teeth in children have to last the longest and there is a graver responsibility at this time to make sure that the fillings are such that they will still be sound in adult life and not merely failures in extracted teeth.

A sound and adequate service must be provided for adults as well as children. The potential students are there, and more could be recruited. The one thing lacking is accommodation for their training. Surely the immediate answer is to build new dental schools or expand existing ones rather than to adopt an experiment which has so many obvious disadvantages. Panic legislation is seldom good legislation, and it is greatly to be hoped that those responsible will pause for thought before allowing emotional issues to override critical judgment to the detriment of all sections of the community.

London W.1. ALEXANDER B. MACGREGOR.

SIR,—Your leader of Oct. 25, like a similar one some months ago, shows how strongly you sponsor the scheme for creating a class of "ancillaries" similar to the school dental nurses of New Zealand. May I put some of the arguments in favour of opposing such a scheme?

You make several assertions which are quite unacceptable to the experienced dental practitioner:

1. Children's dentistry is far from being "simple routine"; rather the reverse is true. It can only be practised successfully by operators with considerable experience—experience which for the sake of *plain* humanity should be acquired through treating adults!

2. The school dental nurses' scheme of New Zealand is not generally recognised to be an unqualified success. It is wasteful of man-power and national resources, and has retarded the development of dentistry in New Zealand. If the money spent on it had been used for professional training, the treatment of all classes in New Zealand might have been much better.

3. During the passage of the Dentists Bill, 1951, through the House of Lords attempts were defeated to make the employment of ancillaries conditional upon their "personal" supervision by qualified dental surgeons. As the Bill stands, it permits the employment of dental nurses exactly as they are being employed in New Zealand—i.e., as operators nominally supervised by a professional man, but working often more than 200 miles distant from the man who is supposed to carry out this "supervision" and who, as a rule, will not see a particular nurse more than about twice a year. If the intentions of the scheme's sponsors and of H.M. Government are to introduce similar practices in this country, then the expression used in your article "A proposal . . . to employ ancillaries in clinics under professional supervision" is grossly misleading. In the absence of such intentions the determined resistance to amend the Bill so as to require "personal" supervision, is inexplicable.

Your readers may not realise that the New Zealand school dental nurse is in no way comparable to medical ncillaries, but is, as the *Journal of the Irish Dental ssociation* (April, 1952) has pointed out, not an ancillary worker at all in the accepted sense of the word, but rather member of a new profession which has been created without the usual safeguards. The most crushing argument against training school dental nurses in this country t present is that more dental surgeons cannot be trained ecause training facilities are lacking (no *new* dental chools have been opened in this country for almost hirty years !), and that the Ministry of Health has so far ntirely failed to explain *how* the creation of training acilities for dental nurses can but interfere with the much more urgent creation of training facilities for dental urgeons.

London, S.W.15. E. ROSENSTIEL.

SIR,—The questionary from the British Dental Associaion asked general dental service practitioners if they were willing to treat school-children in the school dental ervice on a sessional basis as well as in their own practices, being, therefore, in line with joint circular 22/52 (Ministry of Health), 254 (Ministry of Education) addressed to local authorities on June 30. From the replies received which you have analysed, a substantial amount of assistance is evidently available, although it s agreed that it is insufficient to provide complete treatment for every school-child in Great Britain. Nevertheless this reinforcement to the school dental service is particularly important as a short-term policy because the numerical strength of the school dental service is practically the same as it was in 1938, whereas local authorities since 1944 have assumed increased responsibilities to children in secondary schools and to the maternity and child-welfare groups.

In a letter to the *British Dental Journal* of Feb. 5, I reviewed objectively, but not unsympathetically, the question of the New Zealand dental nurses. I pointed out that their training rendered them technically competent in conservative work, but was inadequate to form a correct diagnosis, and that the great weakness in New Zealand was a lack of proper supervision due to local conditions. In spite of pressure from the dental profession, ably reinforced by Lord Webb-Johnson in the House of Lords, the Government have refused to amend clauses 18–20 in the Dentists Bill to tighten up supervision. In fact these clauses are so loosely worded that, according to competent legal opinion, the whole structure of dental practice in this country is capable of being undermined by the introduction of various classes of ancillaries. Public utterances by Ministry officials have not lessened this impression. It is not surprising under these conditions that the British Dental Association have shown little enthusiasm for the Government's suggestions. If the latter do in fact mean what they say, the relevant clauses can be easily amended to ensure that no other ancillaries are contemplated.

Your concluding paragraph does less than justice to the dental profession. The treatment of children, though, of course, largely routine like other forms of practice, offers in the field of orthodontics opportunities for the development of manipulative and scientific skill equal to those in any other branch of dentistry. The real reasons why so large a proportion of practising dentists appear unwilling to help are very different. The dental treatment of children involves great physical and nervous strain, and the more sympathetic the operator the greater the strain. It is pre-eminently a young person's job, and the dental profession is heavily overweighted by the older age-group due to the influx of practitioners in 1921. Moreover, for some inscrutable reason the Government have decreed that payment for the difficult and highly important work of treating children both in the National Health Service and on a salaried basis shall be lower than that for the treatment of adults.

It may be added that, as far as the local government service is concerned, dentistry still remains under direct medical control, opportunities for advancement to really high positions are non-existent, and there is little to attract the young progressive practitioner.

The solution to the problem of children's dentistry is no easy one, and must remain basically a long-term affair, but the following courses suggest themselves. Recruitment of fully trained dentists to the profession should be increased by every possible means. Conditions of pay and employment in the school dental service should be improved. Ancillaries should be limited to the New Zealand type and employed only in the school dental service under adequate supervision. The latter condition, though impracticable in New Zealand, *can* be and *must* be ensured over here. Overseas experiences suggest also that the total output of the ancillary training schools could be absorbed without difficulty in the school service.

London, W.1. E. E. WOOKEY.

ANÆSTHESIA FOR OUTPATIENTS

SIR,—If a relatively junior anæsthetist may comment on the methods of a master, I should like to discuss a few of the points raised by Dr. Bourne in his article of Oct. 11.

1. I feel that many anæsthetists will not accept Dr. Bourne's provocative statement that " outpatient anæsthesia will not be improved so long as nitrous oxide continues to be used." He agrees that the intermittent thiopentone/nitrous oxide and oxygen sequence (described by Broad and Organe before the late war) is widely regarded as ideal for inpatient anæsthesia. Here the nitrous oxide is not present merely " by tradition," nor is it occupying space in the mixture " which would be occupied to better advantage by oxygen." The analgesic properties of nitrous oxide supplement the narcotic properties of thiopentone—in the presence of very adequate oxygenation. If further evidence of the analgesic properties of nitrous oxide is required, one has only to inhale a few breaths of 50% nitrous oxide and oxygen. In outpatients the disadvantage of this technique is the long-continued effect of thiopentone—not the presence of nitrous oxide.

2. Dr. Bourne mentions the disadvantage of salivation caused by cyclopropane. In my hands 50% cyclopropane in oxygen causes most inconvenient salivation in a large proportion of unpremedicated patients. The routine administration of atropine, or its derivatives, would cause unpleasant postanæsthetic symptoms for the ambulant patient.

3. I suggest that the quick induction and the speed of the cyclopropane anæsthesia described by Dr. Bourne are not necessarily advantageous. His account of fifteen children undergoing dental extractions, taking an average of 3 minutes each (including presumably the seating of the patient in the chair, his reassurance, and finally his replacement by another patient), suggests the type of " smash-and-grab " technique deprecated by Gillies [1] and discussed in Dr. Bourne's paper. The replacement of the face mask and potentiation of anæsthesia in the midst of this dental haste, " as when a tooth was broken," must have its dangers.

4. The practised anæsthetist can usually induce nitrous oxide anæsthesia without the patient ever knowing that a mask has been on his face, unpleasantness being reduced to a minimum. This applies also to cyclopropane, though in the technique described by Dr. Bourne the mask is placed on the face at the outset—possibly somewhat frightening to small children who have just been hurried into the dental chair.

5. A sequence taught by Dr. I. W. Magill, and many other authorities,[2] consists in using cyclopropane to supplement nitrous oxide and oxygen. Here, the cyclopropane replaces the thiopentone of Broad and Organe's technique and, by virtue of its speed of elimination, disposes of the disadvantages of giving thiopentone to outpatients. It is known that 10% cyclopropane in oxygen maintains light anæsthesia, whilst 6% cyclopropane in oxygen will produce unconsciousness in the average person.[3] Experience shows that 6%

---

1. Gillies, J. *Proc. R. Soc. Med.* 1945, 38, 235.
2. Gillies, J. Textbook of Anæsthetics. Edinburgh, 1948; p. 297.
3. Hewer, C. L. Recent Advances in Anæsthesia and Analgesia. London, 1948; p. 51.

cyclopropane in a nitrous oxide/oxygen mixture (20–25% oxygen) will maintain light anæsthesia in most cases.

By this method for most outpatient operations induction is with nitrous oxide. Oxygen and cyclopropane are soon introduced, the cyclopropane enabling the percentage of nitrous oxide to be reduced, whilst the oxygen is increased. The nitrous oxide (being analgesic even in the presence of a high percentage of oxygen) supplements the small percentage of cyclopropane. *Cyclopropane is not present in high enough concentration* to cause salivation, nor is nausea and vomiting so common as after inhalation of cyclopropane/oxygen mixtures. A typical "maintenance mixture" would be: Oxygen 1000 c.cm. per min., cyclopropane 200–300 c.cm. per min., nitrous oxide 3000–4000 c.cm. per min. For long-continued administration an absorber may be used. For dental operations a nasal mask relieves the dentist of the worry of a time limitation.

H. BARRIE FAIRLEY.

THE CAUSE AND TREATMENT OF LEG ULCERS

SIR,—While reading Dr. Anning's excellent article (Oct. 25), I was struck by the curious anomaly that leg ulcers are commoner in those who stand at work than in those with sedentary occupations. At first thought this might not seem unexpected; but surely the leg muscles, the motive force of the "leg muscle pump," are more active when one is standing. The muscles of the most immobile of standing workers are in a state of ever-changing tonus to maintain balance; whereas the whole of the musculature of the sedentary worker, below the diaphragm, is comparatively flaccid for hours on end.

I suppose that the explanation is that in these cases the leg muscle pump is rendered useless by inefficient valves, and gravity becomes the most important factor; and thus, when Dr. Anning states that after compression has been applied the patient must be encouraged to walk, the benefits of walking are really only psychological (but no less important for that). To the undeluded physician, however, this should only indicate that well-applied compression can overcome the effects of gravity—not that it can make a valveless pump work.

London, E.17.

ROBERT HIGH.

SIR,—Dr. Anning reiterates his opinion that varicose veins are an uncommon cause of leg ulcers. This is based upon his personal observation of 715 patients, of whom no less than 79% are classed as post-thrombotic whilst a mere 7% are listed as truly varicose. This indeed is a small number; but let us take heart, for I have a feeling that in his endeavour to shift the pendulum of venous opinion Dr. Anning is merely putting the clock back, to conform with the myriad historical references with which his address is so liberally spiced.

I wonder whether he realises just how highly selected his patients are by the time they figure in his statistics. The family doctor has filtered off and successfully treated many of the varicose ulcers before they reach the hospital. In the hospital itself, the varicose-vein clinic achieves swifter results with the varicose ulcers than with their post-thrombotic brethren; and it is these latter—the long stayers—who are likely to be referred to the final dermatological court of appeal over which Dr. Anning so skilfully presides. There, they take their place quietly, uncomplainingly, and most misleadingly in his ætiological histogram of leg ulceration.

Can it be this conditioned bias towards a deep venous causation which makes him exclude varicose veins from his list of sources of failure of *the leg muscle pump*? It is curious that, in quoting a selection of Walker's (1950) figures in support of his thesis, he omits the very ones which demonstrate that superficial varices *alone* can lead to a deterioration of the muscle-pump mechanism.

Indeed, in his remarks on varicose veins Dr. Anning shows himself to be sadly *out of touch with contemporary* specialist opinion. The fact that his series includes 56 patients in whom saphenous ligation either exacerbated, precipitated, or failed to *prevent* ulceration, is merely a painful and poignant commentary on the poor treatment they had received at other hands.

London, W.1.

STANLEY RIVLIN.

SUBLINGUAL HEPARIN

SIR,—We were interested to see last week the report by Mr. Tomich and Mrs. Woollott (p. 888) on the sublingual administration of heparin. In March of this year we published results of a clinical trial of heparin given in this way, and we reported our failure to influence the coagulation-time with as much as 500 mg. of heparin sodium placed under the tongue.[1] *Our findings agreed* with those of McDevitt et al.[2] which were published about the same time in America, but were very different from the results described in the original report of Litwins et al.[3] These authors claimed that sublingual administration of 125 mg. of heparin sodium could be relied upon to prolong the coagulation-time to therapeutic levels for four hours. Indeed it seemed to us that their results suggested that heparin was as efficient sublingually as intravenously.

As heparin is not a fully homogeneous substance or a *single chemical entity, different* batches of the commercial product might show some variation in the predominant molecular size, and therefore in their ability to pass a membrane. Minor differences of this kind, if they do occur, might explain minor differences in the results of observers using different preparations of heparin, and particularly when in addition a different species is used as the test subject, as was done in Tomich and Woollett's experiments. The differences in the results of clinical trial with sublingual heparin were not minor, however, and it is most improbable that a reduction in molecular size accounts for the results of Litwins and his associates.

Royal Infirmary, Glasgow.

A. BROWN
A. C. KENNEDY.

BOOKS INFECTED BY SCARLET-FEVER PATIENTS

SIR,—Your note of Oct. 18 (p. 783) states that a full account of the investigation in Leicester will appear elsewhere; but some comments seem to be worth making even at this stage.

As streptococci are well known to be transmitted by droplet spray it is extremely likely that they will be present in large numbers on books, usually held about 14 in. away for reading, from a patient with an acute streptococcal lesion of the throat. The *selection as* "controls" of Sonne dysentery cases seems puzzling, since two *layers of linen and* three or more blankets usually intervene between the book and the source of *infection. Moreover, transmission* by fingers from lesion to book is far more likely with streptococcal infection.

Will the fuller report adduce *clinical* evidence of spread? *Are we to learn how the pathogens* in the books, themselves lacking any power of locomotion, *are to infect others now that they lack the propulsion formerly* derived from the nasopharynx of their late *host*? Proof of the infection of books we have now *before us*; but this is a far cry from "an investigation in that city to establish the likelihood of patients with scarlet fever transmitting infection to others *through* library books."

Hildenborough, Kent.

3. Litwins, J., Vorzimer, J. J., Sussman, L. N., Applezweig, N., Etess, A. D. *Proc. Soc. exp. Biol., N.Y.* 1951, 77, 325.

SPECIALISTS AND PRACTITIONERS

SIR,—A consultant has said it. Sir Heneage Ogilvie, in his most stimulating address (Oct. 25, p. 820), has clearly shown the dangers inherent in the present system of selecting specialists and the evils of over-specialisation. He sees the general practitioner as the one remaining member of the health service with enough general medical knowledge to view the patient as a whole.

Thoughtful general practitioners will go a step further. If the present trend in the hospital world continues and the general practitioner allows himself to become, as many fear, a sorting clerk to the hospital departments, will not the sick person be completely submerged in the deep waters of scientific medicine ? Those of us who have watched the flow of the tide have been in no doubt as to the outcome, and we have tried to meet it as best we can. Hence the clamour for increased status for the general practitioner; hence the call for a College of General Practitioners.

With the extinction of the great race of general physicians and surgeons—an extinction which seems inevitable—a vacuum will be formed which only the general practitioner can fill. To fill this gap with distinction—nay, even with ordinary competence—the general practitioner must prove his skill; he must have freedom to use some hospital beds, access to pathological and radiological services, and, further, a corporate body to encourage and help him with advice and example.

We should all be profoundly grateful to Sir Heneage Ogilvie for putting the case so clearly.

Dartmouth. R. M. S. MCCONAGHEY.

VITAMIN B_{12} AND ISONIAZID

SIR,—Recently Ata and Tanaka[1] reported that a subcutaneous injection of vitamin B_{12} (0·30 mg. per kg. body-weight) appreciably diminished the acute toxicity of isoniazid in mice. In their experiments a definite increase in the subcutaneous L.D.$_{50}$ dose of isoniazid was obtained when the above-mentioned dose of B_{12} was administered thirty minutes after the isoniazid injection. We have been unable to confirm their results using aqueous solutions of crystalline vitamin B_{12}. Even a 16-fold increase in the dose of B_{12} failed to protect against the acute toxic effects of isoniazid in male albino mice. Isoniazid was administered as a 2% aqueous solution and vitamin B_{12} was injected as a 0·002 or 0·032% aqueous solution. The B_{12} test solutions were checked for qualitative and quantitative content by infra-red and ultraviolet absorption measurements. Dose volumes of the B_{12} solutions injected were 0·30 ml. per 20 g. body-weight. Isoniazid control mice received equivalent volumes of physiological saline subcutaneously instead of B_{12} solution. The results are shown in the following table:

EFFECT OF VITAMIN B_{12} ON TOXICITY OF ISONIAZID IN ALBINO MICE

Subcutaneous 30 minutes after treatment		Subcutaneous isoniazid L.D.$_{50}$ (mg. per kg.)	No. of mice
Agent	Dose (mg. per kg.)		
Saline	..	190 (170–213)	50
B_{12}	0·30	196 (180–214)	50
B_{12}	4·80	185 (167–205)	50

19/20 confidence limits[2] indicated in parentheses.

Neither of the two B_{12}-isoniazid L.D.$_{50}$ doses differed significantly from the saline-isoniazid L.D.$_{50}$.

Among more than fifty compounds screened as possible prophylactics against isoniazid acute toxicity in mice, only barbiturates and some related central depressant agents appeared to offer therapeutically useful protection. Certain thiol compounds, including dimercaprol (BAL), offered only a transient suppressive action in high doses. A large series of other agents, which included carbohydrate metabolites, amino-acids, and vitamins, failed to protect mice unequivocally against the acute toxic effects of isoniazid. These results are to be published in detail elsewhere at a later date.

HALLUX VALGUS

SIR,—I have read with great interest the article by Dr. Hardy and Mr. Clapham.[1] Here in the South of Madagascar I have very often observed hallux valgus in older people who have never worn shoes; it is almost always associated with flat-feet. I have never seen hallux valgus in people under 20 years of age.

Betioky, Madagascar. B. KALCEV.

WITHDRAWAL OF TEACHING

SIR,—I agree that, as you implied in your leading article on Oct. 11, the abolition of the travelling film units of the Central Office of Information is an example of "penny wise and pound foolish."

During the last few years the Ministry of Health has produced six films on the early diagnosis of cancer, specially in order to help general practitioners. These films, which were described in your leading article, have been shown at conferences in many European countries and in Africa, where they were much admired; but I have not yet met a general practitioner in England who has seen one of them, and to make matters worse the Central Film Library has removed the copies from the film department of the British Medical Association. I do not know how much money was spent in producing these films; but if they are not circulated and seen by the practitioners of this country, the money has been largely wasted.

MALCOLM DONALDSON
Chairman, Medical Committee,
Scientific Film Association.

London, W.14.

SIR,—May I join with Dr. Cardew in admiring your leading article on the damage done by the withdrawal of the C.O.I. mobile projection units and the Crown Film Unit.

When the blow fell I wrote to the *Times* drawing attention to the fact that the harm would be felt most severely by those groups, whether of nurses or small study groups, whose financial resources are smallest and whose need for the broadening effects of the film is greatest.

Dr. Cardew pointed out that the money, time, and labour required to make a film, although great, are justifiably expended because the results can be shown to audiences all over the country for as long as the subject remains of interest. An elaborate and expensive film dealing with details of treatment, whether surgical or medical, is likely to have a much shorter useful life than a descriptive film dealing with the clinical appearances of a disorder. In other words, although it is relatively easy to make a well-composed film about a surgical operation, the time and trouble might be better spent tackling the more difficult subject of making films which would increase the clinical experience of medical students, and so improve their diagnostic ability.

One wants to record the clinical history of rare disorders. I think the last cases of tetanus seen at Guy's were in 1948 and seven years earlier than that. Many students never see a case of tetanus. What is needed is a single-bedded side ward, fitted with permanent lighting equipment, to which a patient with tetanus, for example, could be admitted for treatment, and in which films of his condition could be made from time to time. With the permission of the patient, these could be edited into a very useful teaching film.

THE NOTIFICATION OF DISEASE

SIR,—Although, in the light of Professor Bradford Hill's remarks (Oct. 18, 1952), I acknowledge that the comparison I made in my paper did not do justice to the Medical Research Council's inquiry, I still think that the basic contention underlying my remarks is true—that compulsory notification of disease, as being more comprehensive, is a better basis for such an inquiry than other forms of certification.

May I mention two points which were inadvertently omitted from my paper: first, that ice-cream makers and dealers are required to notify the medical officer of health of the occurrence of certain milk-borne diseases in persons living or working in the premises on which the ice-cream is manufactured, stored, or sold; and, secondly, that a copy of any food-poisoning notification received must be sent within twelve hours by the district medical officer of health to the county medical officer.

Exeter. Medical Officer of Health.

ADOPTION

SIR,—In thanking you for your annotation of Oct. 25 on my book *Child Adoption in the Modern World*, may I touch on one or two points where I think it is a little misleading?

Perhaps first I should mention that I wrote my book in a spirit of splendid impartiality, since I then had no connection with the adoption societies. I express myself here too as an ordinary private person and not as representing anything.

Perhaps you believe that opposition to third parties in adoption cases is a kind of crank or partisan attitude on the part of the adoption societies. This is far from being the position, and all informed opinion in the adoption world, so far as I know, is against third-party placements.

The medical practitioner has a special temptation to become an occasional go-between in adoption cases. But these opportunities to do what seems to be a good turn all round are fraught with special perils, and perhaps some doctors still do not realise the serious responsibility they at times incur on behalf of emotionally distressed patients. Most medical men and women experienced in adoption work would, I believe, fully endorse the view expressed by a prominent member of the medical profession who spoke on a television programme in September. He said that he thought private adoptions should be permitted only with the help of a recognised agency. He also said that doctors should not recommend a child to a woman with "nerves," or encourage adoption as a means of keeping a marriage off the rocks. What the adoption worker feels about the participation of a doctor in a third-party adoption he probably owes in some measure to the lead given by other members of the medical profession!

If I may quote you as a witness, it would seem that a doctor's very professional zeal may sometimes lead him astray in adoption matters. You say: "The doctor is obliged to take the welfare of all parties into consideration. His opinion that an emotionally disturbed woman may be helped, sometimes to lasting recovery, by having a child to look after, is not always, or necessarily, ill founded." This attitude is opposed to the adoption principle embodied in the Adoption Act, which says that the court hearing an adoption application must assure itself that "the [adoption] order if made will be for the welfare of the infant." One cannot too strongly stress that the child's welfare takes absolute precedence of the welfare of the would-be adopters. The plea that it is justifiable in any circumstances to use a child to bring about a problematical and perhaps merely temporary cure of an emotionally disturbed woman is a melancholy tribute to the desire of the physician to cure his patient at all costs. But would-be adopters have no rights vis-à-vis the child; their needs, grievous though these may be, establish no sort of claim—in law or sentiment—on a small stranger. On the contrary, the child has a right to be protected in his helplessness.

It is true that when people do not get a child from an adoption society or welfare authority, as often happens, they may get one privately. But this does not mean that it is a good thing. Carefully planned adoptions are the safeguard of the adopters just as much as of the children.

Of course, as you say, the adoption of a baby by affectionate people, even if they are imperfect, is a great blessing to the child. Practically all social workers now agree that private home life is better for most children than a Home. But we have no need to be indiscriminate about it. The choice for the adoptable child need never be the dubious one as between a casually arranged third-party adoption and a Home upbringing. Every deprived baby living in this country who has reasonable health and background has at least twelve sets of worth-while adopters queued up and waiting for him, and any adoption society would be pleased to place him.

One knows there are would-be adopters who do not care to submit to the inquiries that are made before placing both by adoption societies and the adoption departments of local authorities. This resentment is in itself suspect. Some of those who apply to a doctor for a child have already been turned down by an adoption society—not necessarily because they are not nice people, but because they are considered too old, or have not the right accommodation, or something of that kind.

Doctors who have placed children for adoption or who contemplate doing so might be interested to buy a copy of the Adoption Act and of the Regulations made under the Act. The Regulations binding on adoption societies do not, of course, relate to third parties, but they indicate what the law of the land considers is essential procedure in good adoption work. The societies are bound to make inquiries on 61 points relating to the child, his parents, and the adopters. No less than 23 of these questions (about the child's health) must be answered by a doctor.

Unfortunately, adoption is not and never can be a sure-fire mass method of emptying institutions and orphanages, as your reviewer hopes. It is a selective method for certain children. But really there is no vested interest in keeping large numbers of children in Homes.

The practised adoption worker brings to the task at least three things: experience; humility, and the desire to go on learning; and a large number of good contacts with potential adopters, local officials and welfare people, other voluntary organisations, moral welfare workers for mothers and babies, clerics and religious organisations, hospitals, doctors, nursing homes—and other adoption workers. Good contacts are very important indeed, for they help to remove adoption work from the hit-or-miss realm of casual placement and to make it a matter of team-work. If there were no other reason why third parties are undesirable it would be a decisive point against them that they act in isolation and without perspective, as well as without in the majority of cases knowing what they are doing.

The medical profession has a very great deal to give to good adoption work. The help of doctors is important and much valued, and if more of them could give up precious time and consent to sit on adoption society committees the benefit would be enormous. To those busy doctors who already make their services available in an advisory capacity as members of "adoption teams," the adoption societies concerned are, I feel sure, extremely grateful. There should be such a team in every area.

Bromley, Kent. MARGARET KORNITZER.

BARBITURATE POISONING

SIR,—During the past week we have obtained some publicity regarding our "Barbiturate Unit," and we feel that the following information may help to clarify the situation.

The unit, consisting of a small number of beds, will be primarily for the treatment and investigation of cases of *acute* barbiturate intoxication. We are not a unit for the admission of cases of "drug addiction." We should be delighted to admit cases from any doctor in any area, provided he feels that the case is within reasonable travelling distance of the hospital. Admissions should normally be arranged through our admission officer, who is available for emergencies throughout the twenty-four hours.

Before admission, patients should, where necessary, be given the appropriate first-aid treatment, such as artificial respiration or oxygen administration.

FUTURE OF THE OCCUPATIONAL HEALTH SERVICES

SIR,—I am glad that Dr. Lloyd Davies showed in his letter last week how the terms of reference of the Dale Committee precluded them from making sweeping suggestions for a reorganisation of the occupational health services, even if they had felt it desirable to do so. There are, however, certain statements in Dr. Lloyd Davies's letter which I cannot allow to pass, lest it should be thought that the views he expressed were held by all medical members of the Dale Committee.

In his enumeration of the difficulties besetting planners, he states that "employers are responsible for the health, safety, and welfare of their workers." It is true that employers have important legal responsibilities for the worker while at work, but the employer is not the only person with a responsibility. While general practitioners, health departments, and caterers also have responsibilities for making a good and contented worker, surely one of the most important factors is a satisfactory home life. Managerial interest and responsibility is only one aspect of satisfactory industrial relationships.

As regards the attachment of the industrial medical officer to the employer—"an integral part of management"—this is of course only good as long as the doctor, employer, and employee not only play fair but demonstrably do so. I have never seen any evidence to the contrary, but surely it is desirable that the doctor should be independent and feel fully able to proffer his advice without any suggestion of bias.

The imposition of minimum standards does of course postulate some authority with power to impose. But how does Dr. Lloyd Davies know that it would be impossible for a local authority, in conjunction with other interested bodies, to evolve an acceptable scheme of supervision? Medical officers of health, do, I hope, know their manners, but they have learnt to carry out strange tasks in the past.

My most important point of disagreement results from his prognostication that "action based on knowledge will be toward a small, highly skilled cadre of doctors rather than towards unwieldy and untrained regiments." Surely the aim of every specialty should be to bring its special knowledge and experience into the general body of medicine, and if possible make it an accepted part of general medical practice. The occupational health service should not become a closed shop. In any case the diversity and size of industry and its problems, which affect all medical practitioners to some extent, require the coördinated assistance of all kinds of doctors; general practitioners and specialists must all contribute and, frankly, I am looking forward to the not inconsiderable part which I hope the public-health departments will play in the development of industrial medicine and the care of the worker.

The difference between Dr. Lloyd Davies and myself surely lies in the question of execution and not of aim, for we all appreciate the importance of a fit and happy industrial population in a healthy nation. The final shape of the industrial medical service is not yet known and many inquiries and investigations into the problems are necessary. In particular, the position of the small factory requires careful study. At present there is a danger that the presence of small factories may be used as a propaganda weapon by persons who think of industrial relationships as they existed half a century ago. No-one denies of course that there are many small organisations which are slum factories, but they should not be lumped together as undesirable just because they are small.

With our difficulties of man-power and resources, the development of an industrial medical service is likely to be slow. This is fortunate for it provides opportunities for interested parts of the profession to get together. As a medical officer of health I would like to see the public-health department doing some spadework; local reviews of sickness and death rates in relation to occupation should be made, for vital statistics are a very necessary guide. Industrial medicine may or may not be primarily a medical matter, but it is a matter in which the medical profession as a whole must interest itself.

Despite my pleading, I too was a member of the Dale Committee. These opinions are my own and do not necessarily reflect those of my authority.

Sheffield. LLYWELYN ROBERTS

Parliament

Organisation of General Practice

IN the House of Commons on Oct. 30, Mr. H. A. MARQUAND said that the first three years' experience of the National Health Service had revealed defects in the working of the general-practitioner service. Some doctors complained about the large number of patients they were asked to look after, some suggested that they had insufficient opportunities for hospital practice, or insufficient access to modern diagnostic aids in their practice. The younger men complained of the difficulties of entering practice as principals. Patients complained of the time they had to wait in surgeries. Ministers had their complaints, too, especially about the size of the drug bill. When he became Minister of Health, Mr. Marquand thought that an amendment in the method of remunerating general practitioners might help to remedy these defects.

A LOST OPPORTUNITY?

At that time, he continued, a sharp difference of opinion had arisen between the doctors and the Ministers as to whether the findings of the Spens report had been implemented. To get this bone of contention out of the way it was agreed to submit the question to an independent adjudicator. At the same time it was decided to set up a Working Party to suggest a new method of distributing the money, and enable them to advance to an improved service in a better atmosphere. He confessed that the Danckwerts award had surprised him, but when an independent opinion had been sought it must be accepted, and he understood that the money was in course of being paid. What remained was the second part of the bargain, and here he felt an opportunity had been missed.

The Working Party proposed to reduce the size of the maximum list from 4000 to 3500. Was it true, he asked, that the number of patients released from those over-large lists, and made available to other doctors with smaller lists and incomes, was only 500,000? Mr. IAIN MACLEOD, the Minister of Health, interposed that the figure was probably 2 million. Mr. MARQUAND said that was encouraging. But even so 3500 patients was a large number for one doctor to look after. He regretted that no provision had been made to taper the capitation fee. Most of the complaints about the Working Party's report had come from the small-list doctors.

The Working Party had also been asked to make it easier for new doctors to enter practice. He was told that today the number of salaried assistants was 2300 and that in addition there were 500 hospital registrars seeking employment. He agreed that the Working Party had found a useful way of encouraging practitioners to take partners rather than assistants by means of a loading which would not apply to patients attributed to an assistant. Would it not be possible to go further and prohibit the continued employment of assistants by any principal after a certain time? Or would it not be more reasonable to reduce the number of patients who could be attributed to an assistant from 2000 to 1000 or 1500?

Mr. Marquand considered the Working Party's most important task had been to devise ways of stimulating group practice. Yet only one short paragraph in their report mentioned this subject.

GROUP PRACTICE v. FAMILY DOCTOR

Mr. SOMERVILLE HASTINGS had no quarrel with the Danckwerts award, because he believed it essential to raise the status of the general practitioner. On the other hand he quarrelled with the Working Party's report because it did not do enough for the general practitioner. For instance he regretted that the Working Party had not suggested special rewards at the top of the service. He also wished that more had been done to stimulate partnerships. In his view we should not get the best medical service until health centres were developed, and he could only conceive health centres developing among doctors who were working in partnership. Again, unless doctors were working together, we should not promote that minor specialisation which made general practice interesting. One of the ways to get health centres was to help doctors to work in partnership; then persuade a local authority to build or secure a house into which they could transfer their practices; and then later, when the money was available, to attach to that health centre all the other preventive services. It might be possible, he suggested, to add something to the capitation fee of all doctors practising in registered partnerships.

Mr. ANGUS MAUDE found little to object to in the report as a whole, but confessed he was uneasy about the position of the small-list doctors. There was, he thought, great prejudice against them. We heard about elderly doctors and "pin-money" doctors. But he would rather entrust the health of his family to a competent "pin-money" doctor than to one with a list of 3500 who had not enough time for diagnosis and treatment. Admittedly there might be undesirable doctors in this group, but he thought there were many good doctors taking great trouble with their patients. He did not believe that group practice was the ideal at which to aim, but rather a return to the family doctor giving a good family service. Yet at the moment we were probably going further away from it. A small minority of doctors were not giving a proper service, either because their desire for income was greater than their desire to produce a decent service, or because some of them were rather idle. But that, he thought, was a problem with which the medical profession itself should deal. He would rather have a system where the profession had reasonable control over the standard of quality than one where the State had such a firm grip that it could dilute the service as it pleased, lower the quality of its standard, and fiddle the remuneration as it pleased. He thought they had nearly the best solution they could possibly have.

Dr. BARNETT STROSS, on the other hand, was convinced of the importance of group practice. It was, he believed, our essentially British way of trying out a new form of public service. If not ideal, it was certainly one of the best methods by which the general-practitioner service could move forward. He pointed out the difference between the improvement in the service offered by the family doctors as compared with the spectacular improvement recently offered by the hospital service. Everyone was anxious to help the general-practitioner service to play a notable part, and perhaps the most important part of all, in the health service. But what was the good of £100,000 a year as proposed by the Working Party? The least it would cost those forming a group practice to buy a house and alter it would be £5000, and that meant that in any one year only 20 group practices could be helped. The sum offered should be at least £500,000, and it should be awarded not as grants but as loans at low interest. The award allowed doctors a not ungenerous standard of life, and he suggested that the Minister should ask the local executives to help medical practitioners to improve their standard of accommodation for the public in surgeries and waiting-rooms.

IN DEFENCE OF THE MEDIUM LIST

Mr. MACLEOD, replying to the debate, said that something like 2 million people would have to be shuffled in one way or another on the doctors' lists. To ask that number of people to change their doctors was a serious interference with the liberties of the subject, and could not be ignored. The size of the ideal list could not be settled by rule of thumb. We would not necessarily get a better service by levelling the size of lists, and patients' choice of doctor could not be ignored. He deplored the attacks which had been made in professional journals on the big-list man as much as he deplored the sneers at the small-list man. It was unrealistic to suggest that they could move faster and bring down the figure to say 3000 at the present time. To do that we should need more doctors in the industrial areas where the big lists were concentrated.

It was often assumed that the Working Party's task was to help those with a small list. The terms of reference did not say that. The people who were "least favourably placed" were not only the people with small lists, but most particularly those with medium-sized lists, who were not in industrial areas and who perhaps previously had a measure of private practice and were now doing a full job in the health service.

It had been suggested that there should be a flat rate of something like £1; but that would mean giving more money both to the small groups and large groups at the expense of the middle groups. It had also been suggested that they should load the first 1000, but that would make it more difficult to attract doctors to the designated areas, where they were needed if there was to be a really good service. Calculations about the effects of the new proposals on the small-list and medium-list doctors did not take into account three factors. First, they forgot that up to 2 million patients would have to find another doctor. That was bound to make it easier for small-list doctors to increase their practices or join a partnership with someone who had already a big list. Secondly, they forgot the £200 transitional payment which could be claimed during this year while the redistribution was taking place. Thirdly, they made the depressing assumption of a static position in their practices. Younger doctors who had a small list now would not always have a small list, and he did not believe that it was the duty of the State to subsidise them for ever. He frankly admitted that he did not intend to take competition out of medical practice. He believed that we should try to match rewards with effort and achievement. It had never been part of the policy of this Government, he affirmed, to have a salaried service in the medical profession. A sum of £50,000 had been reserved for cases of hardship, and a portion of the final settlement money was to be put aside to meet any particular difficulties. He could not agree that this was charity. He had every sympathy for the small-list man, and indeed with private practice, but it was his duty to encourage doctors to go where they were needed in the health service.

He also believed that the scheme would make it easier to enter practice. The initial practice allowance was an improvement on the fixed annual payment and the reduction in the maximum lists was bound to help. The 2000 patients who could be attributed to an assistant did not qualify for loading, and this was a further inducement to a principal to take an assistant into partnership.

Mr. Macleod confessed that he shared the common confusion as to what was meant by group practice. He therefore proposed to invite Sir Henry Cohen's Committee on General Practice to consider the subject and advise him. In conclusion he said that he made no extravagant claims for the scheme as it stood, nor would he even say that there was no hardship here and there. But he did claim that in all honour the Working Party strove to implement their terms of reference. In his view they had on the whole succeeded, and he asked that the scheme should go forward in goodwill.

New Medical Act Regulations

In the House of Lords on Oct. 28 the EARL OF ONSLOW explained that the Medical Act of 1950 provided that the General Medical Council should prescribe a period of preregistration service for doctors before they went into practice It was originally intended to prescribe a period of 12 months in the Bill itself, but this was amended and the matter was left to the G.M.C., who had, in fact, decided on 12 months as the preregistration period.

Lord WEBB-JOHNSON asked for an assurance that these men or women should be posted without undue delay to these preregistration appointments. There seemed to him to be no provision by which applicants for provisional registration could receive any remuneration, whereas in the old days, a student who was registered and waiting for a house-appointment, could earn his living in some other sphere. The EARL OF ONSLOW said the G.M.C. had published a formidable list of approved house-posts, which he was informed gave every opportunity for the young doctor to find an adequate position when he qualified and left the hospital medical school.

Insanity and the Criminal Law

In the House of Lords on Oct. 29, Lord MANCROFT asked the Government if they would consider setting up a Royal Commission to examine the problem of insanity and the criminal law.

The LORD CHANCELLOR said that this problem had been examined by the Royal Commission on Capital Punishment appointed in 1949. The Government expected that the Royal Commission would include observations on the problem in their report, which was likely to be available within the next few months. In the circumstances the Government did not consider that any occasion arose for appointing a new Royal Commission with the particular function suggested by Lord Mancroft.

QUESTION TIME

Notification of Poliomyelitis

Mr. S. P. VIANT asked the Minister of Health to what extent his department received records of the history as regards vaccination or immunisation of cases of poliomyelitis notified in England and Wales; whether medical officers of health obtained such particulars; and whether such information would be obtained in future in every case of this disease notified.—Mr. IAIN MACLEOD replied: Medical officers of health have been asked to obtain such information about every notified case of poliomyelitis and to send it to a committee set up by the Medical Research Council, including medical officers of my department, which is investigating the subject of inoculation procedures and neurological lesions. It cannot be decided at present whether it will be necessary to go on obtaining such reports in future.

School Dental Service

Replying to a question, Miss FLORENCE HORSBRUGH, Minister of Education, said that the number of school dentists in England and Wales on Oct. 1 was equivalent to 827 full-time officers, an increase of 100 since January last. A further similar increase would bring the service back to its 1948 level, but an equivalent of over 1000 additional dentists would still be needed to give a ratio of 1 dentist to 3000 children.

Cancer Research

Replying to a question, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the Minister did not propose to incorporate into the national medical scheme the cost of fully financing all cancer research. He regarded cancer research as a very suitable field for private generosity which he would not wish to discourage.

Obituary

JOHN ALEXANDER DRAKE

M.D. Lond. F.R.C.P.

Dr. Drake died on Oct. 29 at King's College Hospital, where he had been for many years physician for diseases of the skin and dean of the medical school.

He was born at Clifton, Bristol, in 1878, the son of Alfred Drake, and he received his early education at Malvern College. In 1896 he entered King's College, where he won the Warneford and Junior scholarships and the Sambrooke exhibition. These took him on to the hospital and he qualified in 1902, and obtained a house-appointment under Sir Watson Cheyne.

After taking the M.B. Lond. in 1903 he entered general practice at Tenby, Pembrokeshire. His health had never been robust but this did not prevent him from doing excellent work there. Ten years later, in 1915, he was unfit for military service, but he succeeded in joining the 4th London General Hospital as physician in charge of the medical division. King's College Hospital had moved to Denmark Hill just before the war and the 4th London formed part of the new buildings as well as extending into Ruskin Park as a hutted hospital. Drake's interest in dermatology was enhanced by the opportunity now given him to attend Prof. Arthur Whitfield's clinic regularly. After the war he became a clinical assistant there, having decided to specialise seriously. To this end he took both the D.P.H. and the M.R.C.P., and in 1920 he was appointed assistant physician to the skin department at his old hospital. At the same time he took charge of the venereal diseases department. He was elected a fellow of the Royal College of Physicians in 1926 and soon afterwards became physician in charge of his department.

During these early years he found time to act as assistant editor to the *British Journal of Dermatology and Syphilology* and as secretary to the section of dermatology of the Royal Society of Medicine, and he was one of the few dermatologists who have served as examiners in medicine to the Conjoint Board. He held the appointment of vice-dean at King's College Hospital Medical School for some twelve years and of dean from 1932 until his retirement in 1937.

S. T. writes: "Drake's rare contributions to the medical journals were characterised by the great care which he showed in all he undertook. But his real interest lay in his own hospital and particularly in its medical school. That he held the appointments of vice-dean and dean for so long is testimony of the trust placed in him by his colleagues. No-one ever had cause to regret this trust, whether patient, student, or friend. His chronic ill health had never warped his kindly outlook; his quiet voice and friendly smile will be long remembered."

In 1908 Dr. Drake married Lorna, daughter of Mr. C. J. Stewart, who survives him.

Major-General MITCHINER

Lieut.-General F. Harris writes: The great services of Major-General P. H. Mitchiner to the Territorial Army, both before and during the war, have already been outlined in your columns; and I should like to endorse all that has been said. Nevertheless I feel that it is appropriate that I, as director-general of Army Medical Services, should add my personal tribute to a great and loyal officer of the R.A.M.C.

"I first met him in 1934 at a weekend training exercise at Brighton, where I had gone as a Regular R.A.M.C. officer to help the Territorial medical officers with their training; but I soon found that Colonel Mitchiner, as he then was, and the officers trained by him knew at least as much about the tactical handling of field medical units as I did. Ever since, he and I have been friends and latterly close friends; and a wonderful friend he was, not only to me but to the whole of the R.A.M.C., both Regular and Territorial.

"From the end of the war until his death he was, as adviser to the D.G.A.M.S., his right-hand man on all matters concerning the T.A. Medical Service. In this responsible task he was of the greatest help; and his wide knowledge of the Territorial Army and indeed, it seemed, of every officer in it, were invaluable. His grasp of training problems was remarkable; his comments were always candid and outspoken but mellowed by wit and a sense of fun. He never spared himself, and during the last few years, though his health was far from good, he visited during the training season numerous T.A. units throughout the United Kingdom, giving advice to the officers in command and taking part in their social activities. The present high standard of training of the T.A. Medical Services is in large measure due to his enthusiasm, knowledge, and personality. Mitch was a great and loveable personality who will be missed by the whole of the Army. We shall not soon see his like again."

R. O. L., who worked under Mitchiner as house-surgeon, registrar, and resident assistant surgeon at St. Thomas's Hospital, writes:

"Undoubtedly he was a brilliant teacher and his own peculiar rhetoric left an indelible imprint on the student mind. But his teaching extended beyond the classroom, out-patient clinic, and ward round. Being essentially practical, he taught also in the operating-theatre. He believed that a student should perform at least one operation; and how many of his students remember the thrill of that first removal of the hernial sac under the expert guidance of P. H. M. in the rôle of assistant? To the house-surgeon, with operating opportunities already sadly diminished by the influx of registrars, the arrival of his junior chief for the evening acute appendix constituted the highlight of 'major week.' Like as not, it would be followed by the genial command, 'Get on with it, Boy.' To the registrars he displayed the same generosity and encouragement in so far as his then limited bed complement allowed, and when the time came for them to move on, his recommendation carried great weight, no matter where the next appointment lay, for he seemed to know everybody. To his juniors Mitchiner's outstanding characteristic was his loyalty and this, amongst many great qualities, will long remain an affectionate memory to the many St. Thomas's men who worked under him."

Births, Marriages, and Deaths

BIRTHS

BARCLAY.—On Oct. 23, at the Women's Hospital, Nottingham, to Cecilia, wife of Mr. Robert Barclay, F.R.C.S.—a son.

FOX.—On Oct. 25, at the London Hospital, to Kathleen (née Welply), wife of Dr. D. G. R. Fox—a daughter.

JANNEY.—On Oct. 24, at King's College Hospital, London, to Susan Marguerite (née Müller), wife of Dr. B. A. Janney—a son.

RYDER RICHARDSON.—On Oct. 27, at The Beeches, Saxmundham, to Eleanor (née Mosse), wife of Dr. J. P. Ryder Richardson—a son.

SAUNDERS.—On Oct. 24, at Bushey Maternity Hospital, to Nancy (née Janes), wife of Dr. D. R. S. Saunders, M.R.C.P.—a son.

STENHOUSE.—On Oct. 29, at the Westminster Hospital, to Joy (née Crouch), wife of Mr. A. B. Stenhouse, M.R.C.O.G.—a daughter.

MARRIAGES

[illegible]—On Nov. 1, John Kingston Baker, M.R.C.O.G., [illegible] t. Stephen's, Canterbury, to Pamela [illegible] Canterbury.

[illegible] 25, John Cordner Foster, M.B., of [illegible] on Rogers, of Chatham.

DEATHS

CONNELL.—On Oct. 31, William Kerr Connell, M.B. Glasg., F.R.C.S., F.R.F.P.S., of Wellshot Drive, Cambuslang, Glasgow, aged 58.

DRAKE.—On Oct. 29, at King's College Hospital, John Alexander Drake, M.D. Lond., F.R.C.P., D.P.H., consulting physician for diseases of the skin, King's College Hospital, and sometime Dean of the Medical School.

JOHNSON.—On Oct. 30, William Crosby Johnson, M.B. Victoria, of Mayfield Lodge, Haslemere, late of Manchester and St. Andrews, aged 77.

MALONE.—On Oct. 22, at Mid-Herts Hospital, St. Albans, William Aloysius Malone, M.R.C.P.I., late Colonial Medical Service.

Notes and News

GENERAL PRACTICE IN LONDON

IN London the number of general practitioners on the executive council's list increased from 2005 at the end of March, 1949, to 2204 at the end of March this year. This is revealed in the executive council's report for 1951-52,[1] which also shows that the average number of patients per list was 1620 on April 1 this year, compared with 1656, 1670, and 1638 on April 1 in the years 1949-51. In 1951 the average number of patients per list ranged from 490 in Hampstead to 2886 in Battersea. During the year 1951-52 practices were disposed of as follows: vacancies advertised, 12; practices dispersed, 39; practitioners with no patients, 10; practices transferred to "logical successor," 36; small practice vacancy, not advertised, 1.

W.V.S. APPEAL

THE Women's Voluntary Services have issued a national appeal for clothing. "W.V.S. wants any type of clean clothing—not only to meet big emergencies such as floods and fires, but also so that we may be able to help the many calls made upon us daily by people in real trouble. The old-age pensioner, the 14-year-old schoolgirl whose mother has died and who is keeping the home together for her father and three younger children, the family where ill-health has prevented the father from working—all are going through a sad and difficult time which a little assistance with clothing can help to alleviate. We are asking everyone in the country to look into their cupboards and drawers and turn out what they can spare in the way of clothing, linen, blankets, shoes, and bits and pieces of wool which can be knitted into small squares and joined up to make blankets. W.V.S. work-parties will mend and alter anything."

Parcels will be accepted at any W.V.S. office or at the organisation's headquarters, 41, Tothill Street, London, S.W.1.

University of Cambridge

On Oct. 11 the following degrees were conferred:

M.D.—M. O. J. Gibson, Portia G. Holman, R. G. Law, I. C. K. Mackenzie.

M.B., B.Chir.—*Andrew Fairley, *J. D. Richardson.

* By proxy.

Royal College of Surgeons of England

On May 5 the Queen will lay the foundation stone of the college's new buildings which will replace the museum destroyed by enemy action and also house the Nuffield College of Surgical Science.

Society of Apothecaries of London

Dr. H. Seaward Morley has been elected senior warden, and Sir Cecil Wakeley junior warden.

Osler Club of London

Prof. Henry E. Sigerist will speak on Medical History in Medical Education at a meeting of this club to be held on Friday, Nov. 21, at 7.45 P.M., at 11, Chandos Street, W.1.

New Neurosurgical Unit

Viscount Waverley, F.R.S., will open the Guy's-Maudsley Neurosurgical Unit at the Maudsley Hospital, Denmark Hill, London, S.E.5, on Thursday, Nov. 20, at 3 P.M.

International Pharmacopœia

The eleventh session of the World Health Organisation's expert committee on the International Pharmacopœia opened on Oct. 27 at Geneva. For the eleventh time, Dr. C. H. Hampshire (London) was elected chairman, by acclamation. This "enthusiastic tribute," his colleagues said, went to the man who had been principally responsible for the successful publication of the *International Pharmacopœia*. Other officers appointed were: Prof. H. Flück (Zürich) vice-chairman, and Dr. T. Canbäck (Stockholm) and Dr. L. C. Miller (New York) rapporteurs. In his opening statement to the committee, Dr. Pierre Dorolle, deputy director-general of W.H.O., reported that since the publication of vol. I of the *International Pharmacopœia* in English and in French a number of member States of W.H.O. and national pharmacopœia commissions had indicated that they were using the book in establishing or revising their own national pharmacopœias. Publication of vol. II would be a further important step in giving unified standards for important drugs.

Royal College of Physicians of London

At a quarterly comitia of the college held on Oct. 30, with Sir Russell Brain, the president, in the chair, Dr. Geoffrey Bourne, Dr. E. C. Dodds, Dr. Robert Platt, and Dr. J. T. Ingram were elected councillors; Dr. A. Feiling was elected representative on the Committee of Management; and Sir Russell Brain, Sir Harold Boldero, Dr. W. G. Barnard, Dr. A. M. Cooke, and Sir Allen Daley were re-elected members of the Standing Joint Committee of the three Royal Colleges.

The following candidates were elected to the membership:

J. A. Balint, M.B. Camb., Charles Berman, M.D. Witwatersrand, S. O. Boldy, M.D. Lond., T. H. Bothwell, M.B. Witwatersrand, P. D. Bryant, M.D. Lond., A. R. Buckley, M.B. Camb., E. J. M. Campbell, M.D. Lond., T. B. Cullity, M.B. Adelaide, R. A. Dale, M.B. Melb., H. E. F. Davies, M.D. Lond., W. E. B. Edge, M.B. Witwatersrand, A. W. H. Evans, M.B. Lpool, B. J. S. Harley, M.D. Lond., Gavin Hildick-Smith, M.B. Camb., B. I. Hirschowitz, M.B. Witwatersrand, D. G. Julian, M.B. Camb., L. H. Klugman, M.B. Witwatersrand, C. D. Lacey, M.B. Camb., W. L. B. Leese, B.M. Oxfd, Mohamed Ajawad Macan-Markar, M.D. Lond., Lisa E. Mandelbaum, M.B. Brist., Jamshed Sorab Moos, M.D. Bombay, L. M. Reid, M.B. Melb., H. R. C. Riches, M.B. Lond., S. J. G. Semple, M.B. Lond., N. K. Shinton, M.B. Birm., Premji Valji Thacker, M.B. Bombay, A. B. Tompkins, M.B. Lond., S. M. Vine, M.B. Camb., Geoffrey Walker, M.B. Lond., P. R. Walsh, L.R.C.P., Glyndwr Walters, M.B. Brist., D. G. C. Whyte, M.D. Belf., major R.A.M.C., G. M. Woodwark, M.B. Camb., C. R. Woolf, M.D. Cape Town.

Licences to practise were conferred on the following 123 candidates (95 men and 28 women) who have passed the final examination of the Conjoint Board:

C. W. M. Adams, H. R. Alpin, Ursula M. Anderson, J. L. Andrews, J. A. R. Anson, D. T. C. Barber, D. W. Barnes, I. R. Beale, J. K. H. Benson, S. W. Bissell, Stanford Bourne, A. J. Bowdler, J. A. D. Briggs, J. J. Brown, J. R. G. Brown, H. P. Charles, Rabindranath Das Choudhury, C. S. M. Chown, Evelyn Coates, J. H. Corbett, B. J. Cremin, L. M. Davis, J. C. Denmark, Ludlow Essex, Anne C. Evans, M. D. C. Evans, John Fairley, Patricia M. Firkins, Margaret Fisher, W. A. Forrest, J. M. Foster, A. I. Fram, Hannah French, Anna L. Frenkiel, G. R. K. Frost, R. E. Fryer, H. G. Gage, R. A. Gawn, H. M. Georgeson, R. B. Glover, G. R. Grant, D. J. Green, J. M. S. Grieve, Elizabeth A. Grimditch, E. H. L. Harries, Joyce Harrison, M. N. Harrison, Derek Harvey, Alan Haylock, Natalie J. Holloway, H. A. Hosking, Neville Howard, C. K. Hudson, Kathleen M. Huntington, C. F. Hutchison, I. B. Johnson, H. S. Jones, H. D. Jones, T. P. Jupp, Patricia M. Kenney, J. B. Kenyon, D. W. King, J. R. Kirkup, W. R. Kynan, S. R. S. Laing, Lesley P. Leader, Rachel E. Lee, Monica C. Lewin, R. J. Lewis, H. E. Lichtenstein, W. J. McCall, Kathleen M. McCartie, Thomas McCormick, I. R. McDonald, J. U. MacWilliam, W. B. Manley, R. A. Matthews, P. D. Meers, D. C. Morrell, T. F. Morris, R. J. Murray, M. R. Newell, A. S. Nicholas, F. I. Partington, Naomi I. Penfold, D. E. Phillips, Grace D. Pinkerton, A. J. Platts, J. F. W. Rail, J. E. Rees, H. F. Reichenfeld, J. W. Rentoul, C. E. Rhodes, W. A. G. Roper, A. D. Rowlands, J. F. Ryan, Mary S. Shenai, Eva H. Short, Anne M. Shuffrey, Elizabeth L. Siddle, I. F. Smith, D. N. Stathers, Kathleen M. Stevenson, J. W. Strain, J. F. Sturridge, J. H. Swallow, E. M. Sycamore, Eva S. Szmulewicz, Audrey M. Tabor, B. D. Thomas, Constance P. F. Thomas, Heather B. Thompson, Lorna G. Tolchard, B. L. M. Turner, J. R. Turner, N. D. Walsh, David Watkins, J. H. White, Roy Wilton, R. P. Wise, A. R. Worters, D. A. Wright, J. D. Wright.

Diplomas were conferred on those named in the report of the meeting of the Royal College of Surgeons in our issue of Oct. 18 (p. 789). The following diplomas were also conferred:

D.M.R.-D.—W. A. Copland, R. S. Crone, E. O. Field, J. V. Goodman, R. G. Grainger, Dinah C. M. Henderson, Maurice Hurwitz, Sarva Prakash Kumar, J. W. Laws, J. C. Linn, Gopendra Nath Mukherjee, R. W. Wilkinson, S. F. Wyner.

D.M.R.-T.—Daphne S. A. Anderson, P. B. Kunkler, G. D. Smith.

British Hospitals Contributory Schemes Association (1948)

The annual conference of the association was held in Cardiff on Oct. 23 and 24 under the presidency of Mr. Henry Lesser. The speakers included Dr. Ffrangcon Roberts who said that in his opinion there was a lack of research and of health education. If people were properly informed about immunisation and other preventive measures they would be able to help themselves more and cost the National Health Service less.

Fulbright Travel Grants

The United States Educational Commission in the United Kingdom are offering these grants to citizens of the United Kingdom and Colonies who wish to visit America for an academic or educational purpose, such as study, research, or lecturing, during 1953–54. The grants will cover the cost of direct travel between the candidate's home in the United Kingdom or Colonies and the destination in America, but since the funds of the commission are in non-convertible sterling, it is not possible to offer grants for maintenance, tuition, or incidental expenses within the United States. Further particulars may be had from the commission at 55, Upper Brook Street, London, W.1.

Charterhouse Rheumatism Clinic

Sir Adolphe Abrahams will deliver the Gilbert Scott lecture on Thursday, Nov. 20, at 5 P.M., at the clinic, 54, Weymouth Street, London, W.1. He will speak on the Simplicity and Profundity of Rheumatism. Further particulars will be found in our advertisement columns.

Medical Art Society

At a meeting of this society, to be held on Thursday, Nov. 13, at 8 P.M., at 11, Chandos Street, London, W.1, Mr. Roland Penrose will talk on Modern Painting.

Helping the Patient to Read

The Miller General Hospital, Greenwich, has installed a Pilgrim microfilm reader which throws reading matter on the wall or ceiling. The patient who cannot use his hands can operate the instrument by pressing a lever to advance or retard the pages. Libraries of films of books for adults and children are available. The instrument is made by Educational Productions Ltd., 17, Denbigh Street, S.W.1. A similar American projector was described in our columns some years ago (1945, ii, 31).

Medical Women's Federation

In celebration of its 35th anniversary the Medical Women's Federation held a congress in London last weekend. After the opening on Saturday morning by Helen Duchess of Northumberland, the Christine Murrell memorial lecture was delivered by Dame Hilda Lloyd, who spoke on Domiciliary Midwifery. Saturday afternoon was devoted to the meeting reported on p. 930, and on Sunday there were clinical and other demonstrations at hospitals and laboratories.

A dinner on Saturday evening was attended by several hundred members and many guests. Sir Cecil Wakeley, P.R.C.S., proposing the Medical Women's Federation, said he thought that medical women were still not accorded the equality they ought to have. He had welcomed the appointment of a woman examiner for the Primary Fellowship, and he looked forward to women examining for the Final Fellowship. The present congress was a large and representative gathering, and the federation had nearly as many members as the Royal College of Surgeons had fellows. Moreover, some departments of medicine were better run by women than by men. Why, for example, were the maternity and child-welfare services not run by women, and why was there only one woman medical officer of health? Women could teach their subjects better than men. His own first house-surgeon, a woman, had been regarded with misgiving but had taught him more about patients than anyone else had done. And every practising doctor had got to be a psychologist and learn how to treat patients. Dr. Doris Odlum, the president, said that, as the war had prevented the federation from celebrating its first 25 years, it was celebrating its first 35 instead. The women who founded it certainly had no thought of separation—no sense of grievance. Then and since, the federation had had help and kindness from the British Medical Association and 100% loyalty in the fight for equality for women. Attempts had been made to get women to undercut men; but the women too had played fair; and their solidarity had enhanced the dignity and status of the whole profession. As a minority of 1 in 10, women doctors found it difficult to get full representation on committees and the like; and there was a place for a minority group which could express the group's point of view. With their practices preponderantly (though by no means wholly) among women, members of the federation were apt to get a rather different view from that of men, and Dr. Odlum believed they were making a very real contribution to medicine and especially to social medicine. This was done partly through the evidence presented by the council at inquiries; and service on the council, with its 65 members, had an additional value in helping members to look at subjects nationally. In all these years the federation had never had a congress for combined scientific and social activity; but the success of this one suggested that it would not be the last. The toast of The Guests was proposed in friendly terms by Dr. Janet Aitken, and Miss Patricia Hornsby-Smith, parliamentary secretary to the Ministry of Health, responded.

EMERGENCY BED SERVICE.—In the week ended last Monday, applications for general acute cases numbered 970. The proportion admitted was 92·6%.

The Order of the Crown of Johore of the rank of Data Paduka Mahkota Johore, has been conferred upon Dr. H. B. C. Wallace, State physician to the Sultan of Johore.

Diary of the Week

NOV. 9 TO 15

Monday, 10th

London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1
5.15 P.M. Dr. Henry E. Sigerist (Yale): Galen's *Hygiene.* (First of five Heath Clark lectures.)

Royal Institute of Public Health and Hygiene, 28, Portland Place, W.1
4.30 P.M. Major-General H. C. D. Rankin: Review of Army Health. (Blackham lecture.)

Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Prof. T. J. Bosworth, D.V.S.M.: Pathogenesis and Control of some Diseases of Newborn Animals.

Institute of Psychiatry, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel: Lecture-demonstration.

Royal Eye Hospital, St. George's Circus, Southwark, S.E.1
5 P.M. Prof. Arnold Sorsby: Criteria for Diagnosis of Hereditary Affections.

Medical Society of London, 11, Chandos Street, W.1
8.30 P.M. Meeting of fellows. Mr. Rodney Smith, Mr. Guy Blackburn: Acute Intestinal Obstruction.

Tuesday, 11th

Royal College of Physicians, Pall Mall East, S.W.1
5 P.M. Prof. A. A. Moncrieff: Infection in the Newborn Baby. (Charles West lecture.)

London School of Hygiene and Tropical Medicine
5.15 P.M. Dr. Sigerist: *Regimen Sanitatis Salernitanum* and some of its Commentators. (Second of five Heath Clark lectures.)

Royal Society of Medicine, 1, Wimpole Street, W.1
8 P.M. *Section of Psychiatry.* Dr. G. Garmany, Dr. H. J. Shorvon, Dr. S. Lowy: Abreaction.

Institute of Dermatology, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. C. O. Carter: Genetics.

West End Hospital for Nervous Diseases, 73, Welbeck Street, W.1
5.30 P.M. Dr. Gerald Parsons-Smith: Neurological demonstration.

Chelsea Clinical Society
8.30 P.M. (South Kensington Hotel, 41, Queensgate Terrace, S.W.7.) Mr. Richard Eve, F.R.I.B.A.: Architecture and Health.

Manchester Medical Society
5 P.M. (University of Manchester.) *Section of Surgery.* Mr. H. Bolton: Surgery of the Hand.

Wednesday, 12th

London School of Hygiene and Tropical Medicine
5.15 P.M. Dr. Sigerist: Quest for Long Life in the Renaissance. (Third of five Heath Clark lectures.)

Royal Society of Medicine
4.30 P.M. *Section of Physical Medicine.* Future Rôle of Occupational Therapy in Rehabilitation.
8 P.M. *Section of Proctology.* Mr. O. Lloyd-Davies: Diverticulitis. (Presidential address.)

Royal Eye Hospital
5.30 P.M. Mr. L. H. Savin: Surgery of the Eyelids, Lacrimal Sac, and Orbit.

Royal Institute of Public Health and Hygiene
3.30 P.M.: Dr. J. W. Starkey: Caring for the Very Young Child.

Institute of Dermatology
5.30 P.M. Dr. H. Haber: Diagnosis by Biopsy and Cytology.

Institute of Urology, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Mr. J. D. Ferguson: Prostatic Cancer.

Harveian Society of London, 11, Chandos Street, W.1
8.15 P.M. Sir Clement Price Thomas: Rôle of Surgery in Treatment of Pulmonary Tuberculosis.

University of Oxford
5 P.M. (Radcliffe Infirmary.) Dr. E. E. Pochin: Radio-iodine in the Diagnosis and Treatment of Thyroid Disease. (Litchfield lecture.)

Manchester Medical Society
4.30 P.M. *Section of Pathology.* Dr. L. Parker, Mr. G. K. Tutton: Cerebral Abscess.

Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, C.2
5 P.M. Prof. A. C. Frazer: Causes and Effects of Defective Intestinal Absorption. (Weild lecture.)

Thursday, 13th

Imperial Cancer Research Fund
5 P.M. (Royal College of Surgeons, Lincoln's Inn Fields, W.C.2.) Prof. M. J. Stewart: Synovial Tumours, Simple and Malignant.

London School of Hygiene and Tropical Medicine
5.15 P.M. Dr. Sigerist: John Peter Frank (1745–1821), pioneer in Social Medicine. (Fourth of five Heath Clark lectures.)

Royal Society of Medicine, 1, Wimpole Street, W.1
5 P.M. *Section of Ophthalmology.* Prof. W. J. B. Riddell: Stenosis of the Tear Duct in Babies.

Royal Eye Hospital
5.30 P.M. Miss M. Savory: Newer Therapeutic Measures.

St. George's Hospital Medical School, Hyde Park Corner, S.W.1
5 P.M. Dr. M. A. Partridge: psychiatry lecture-demonstration.

Institute of Dermatology
5.30 P.M. Dr. R. W. Riddell: Skin Infections due to Yeast-like Organisms.

Institute of Obstetrics and Gynæcology
2 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Dr. Denis Hill: Puerperal Insanity.

Alfred Adler Medical Society
8 P.M. (11, Chandos Street, W.1.) Dr. T. A. Werner: Principles of Psychodynamics in Psychotherapy.

University of Oxford
8.30 P.M. (Wingfield-Morris Orthopædic Hospital.) Sir Harry Platt: Significance of Anatomical Findings in Open Operations in Congenital Dislocation of the Hip.

Liverpool Medical Institution, 114, Mount Pleasant, Liverpool, 3
3 P.M. Mr. A. Rocyn Jones: Evolution of the Treatment of Joint Tuberculosis and the Influence of Hugh Owen Thomas. (Hugh Owen Thomas lecture.)

Honyman Gillespie Lecture
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. I. Simson Hall: Cancer of the Larynx.

University of St. Andrews
5 P.M. (Medical School, Small's Wynd, Dundee.) Mr. T. McW. Millar: Chronic Ulcerative Disease of the Colon.

Friday, 14th

London School of Hygiene and Tropical Medicine
5.15 P.M. Dr. Sigerist: Changing Pattern of Medical Care. (Last of five Heath Clark lectures.)

Royal Eye Hospital
4.30 P.M. Mr. A. J. Cameron: Red Eye and its Differential Diagnosis.

Institute of Dermatology
5.30 P.M. Dr. R. T. Brain: Epithelial Tumours.

Lloyd-Roberts Lecture
4.30 P.M. (St. Mary's Hospitals, Whitworth Street West, Manchester.) Prof. Miles Phillips: Percivall Willughby, Gentleman: Man-Midwife of the 17th Century.

Saturday, 15th

Biochemical Society
10.30 A.M. (London School of Hygiene and Tropical Medicine.) Symposium on Immunochemistry.

Appointments

Caldwell-Nichols, M. A., M.B. Edin., D.M.R.D.: asst. radiologist (S.H.M.O.), York A and Scarborough group.

Coulter, H. H., M.B. Belf.: appointed factory doctor, Westbury-on-Trym district, Gloucestershire.

Douglas, Mary, M.D. Edin., D.M.R.T.: consultant, radiotherapy department, Royal Infirmary, Edinburgh.

Duncan, J., M.B. Aberd., D.M.R.D.: radiodiagnosis department, Royal Infirmary, Edinburgh.

Greening, W. P., F.R.C.S.: consultant surgeon, Royal Cancer Hospital, London.

Hill, T. W., M.D. Glasg., D.P.H.: asst. school M.O., Middlesbrough.

Hood, W. G., M.B. St. And., D.L.O.: asst. E.N.T. surgeon, Glasgow E.N.T. Hospital.

Mayer, Helen, M.R.C.S., M.R.C.O.G.: part-time obstetrician and gynæcologist (consultant), The Mothers' Hospital (Salvation Army), London.

Radley-Smith, E. J., M.D., M.S. Lond., F.R.C.S.: asst. surgeon (consultant), Royal Free Hospital, London.

Sloan, J. B., M.B. Glasg.: appointed factory doctor, Southampton district.

Summers, Frank, M.B. Lond., D.P.H.: deputy M.O.H., Tottenham.

Manchester Regional Hospital Board:

Knowles, E. W., M.CH.ORTH. Lpool, F.R.C.S.E.: consultant orthopædic surgeon i/c orthopædics and accident services, Wigan and Leigh hospitals.

Martin, A. A., L.R.C.P.E., D.P.M.: consultant psychiatrist, Barrow and Kendal areas and Lancaster Moor Hospital.

Milner, E. A., M.B. Durh., D.A.: consultant anæsthetist, Blackburn and district hospitals.

Russell, J. Y. W., M.B. Edin., F.R.C.S.E.: consultant (asst.) general surgeon, Preston and Chorley hospitals.

Silverman, Maurice, M.D. Leeds, D.P.M.: consultant psychiatrist, Blackburn and Burnley hospitals.

Smith, A. E., M.B. Edin., D.A.: consultant anæsthetist, Wigan and Leigh hospitals and Wrightington.

Stalker, Randal, M.B. Edin.: tuberculosis physician, Blackburn and district hospitals.

Warrington, H. C., M.B. Manc., F.F.R., D.M.R.T.: consultant radiotherapist, Christie Hospital and Holt Radium Institute, Manchester.

Oxford Regional Hospital Board:

Rydlewski, Stanislaw, M.B. Polish School of Medicine, D.P.M.: asst. psychiatrist (S.H.M.O.), St. Crispin's Hospital, Duston, Northants.

Thompson, Robert, M.B. Belf., D.P.M.: consultant psychiatrist, St. Crispin's Hospital, with duties in the child-guidance clinics of the Northampton area.

Walker, Oliver, M.D. Lpool, D.A.: consultant in anæsthetics, hospitals of the Aylesbury-High Wycombe area.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

THE FUTURE OF SURGERY IN THE TREATMENT OF SPONTANEOUS CEREBRAL HÆMORRHAGE*

MURRAY A. FALCONER
M.Ch.N.Z., F.R.C.S., F.R.A.C.S.
DIRECTOR, GUY'S-MAUDSLEY NEUROSURGICAL UNIT, GUY'S HOSPITAL, LONDON

SPONTANEOUS cerebral hæmorrhage is common and often fatal. It may present in one of two main forms: (1) *intracerebral hæmorrhage* characterised by abrupt onset of severe headache followed quickly by drowsiness and even coma, and by the rapid development of signs of focal cerebral damage, such as hemiplegia, aphasia, or hemianopia; and (2) *subarachnoid hæmorrhage* characterised by a similar sudden onset of cerebral symptoms but differing in that there is usually little or no evidence of focal cerebral damage apart from cranial nerve lesions, such as a third-nerve palsy or a subhyaloid hæmorrhage. In subarachnoid hæmorrhage blood is found in the cerebrospinal fluid (C.S.F.) on lumbar puncture, whereas in intracerebral bleeding the C.S.F. may be either clear, xanthochromic, or bloodstained, according to the extent to which blood has leaked into the ventricular or the subarachnoid spaces. Either form of bleeding can affect a person at any age, although both are seen more often between the ages of 40 and 60 (Hyland 1950, Falconer 1951). Both have hitherto been regarded as "vascular accidents" outside the scope of any direct intervention, and consequently have been treated routinely only by rest in bed in the hope that bleeding would cease spontaneously and not recur.

With such conservative treatment, however, the mortality from both forms of cerebral hæmorrhage is high. Precise figures relating to primary intracerebral bleeding (as distinct from cerebral thrombosis) are not available; but nearly all these patients die, and cerebral hæmorrhage ranks predominant as a killing disease of the nervous system (Wilson 1940). As regards subarachnoid hæmorrhage, many workers have pointed out that among hospital patients the mortality-rate is generally 50–60%, and that many of those who recover are left disabled (Hyland 1950, Falconer 1951, Mount 1951). An important factor is the frequency of recurrent attacks; about a third of patients who reach hospital die from their initial attack, and nearly half the survivors subsequently develop a recurrent attack while they are still in hospital, with further loss of life (Magee 1943). These recurrent attacks reach their peak between two and four weeks from the first attack, but the possibility of recurrence remains for months and years. Ask-Upmark and Ingvar (1950) have summarised the position by saying that of 5 patients who develop subarachnoid hæmorrhage 3 will probably die, 1 will be left crippled, and only 1 will make a good recovery.

ÆTIOLOGY OF SPONTANEOUS CEREBRAL HÆMORRHAGE

If the mortality of cerebral hæmorrhage is to be lessened, we must first know its common causes and how they can be recognised during life. In this connection the distinction between intracerebral and subarachnoid forms of bleeding is a secondary consideration, for the same causal lesion may produce both types.

Intracerebral hæmorrhage.—The chief cause of primary intracerebral bleeding is rupture of an atheromatous artery in a person with high blood-pressure, and in most instances this occurs in late middle life. The syndromes of rupture of the lenticulostriate arteries in relation to the internal capsule and of the perforating arteries in the pons are well known, but they are really the terminal events of widespread disease processes that remain outside the scope and possibilities of surgery. Other lesions, however, may also cause intracerebral bleeding, and these lesions, which include aneurysm, vascular malformation, and occasionally even a vascular cerebral tumour, although in the aggregate not so common as rupture of an atheromatous artery, account for many cases of apoplexy not only in young persons but also in the elderly. Sometimes no source for the bleeding is apparent even at necropsy.

Subarachnoid hæmorrhage.—As regards subarachnoid hæmorrhage, the commonest cause is rupture of an intracranial aneurysm and this cause accounts for about 75–80% of cases (Richardson and Hyland 1941, Falconer 1951). Vascular abnormalities account for 5–10% of cases, and usually in the remainder no source for the bleeding can be demonstrated (Richardson and Hyland 1941). Rupture of an atheromatous vessel possibly accounts for some of these cases and occasionally a vascular cerebral tumour first manifests itself in this way.

Now two of the causes of cerebral hæmorrhage, aneurysms and vascular malformations, deserve special consideration for they are common, can be readily recognised and located during life, and are remediable by surgical treatment.

Intracranial aneurysms are saccular or "berry-shaped" pouches generally situated in the angle of branching of a major cerebral artery. Once mistakenly subdivided into congenital and arteriosclerotic varieties, they are really all acquired lesions which develop as a result of degenerative processes affecting the arterial wall at a site already weakened by a congenital deficiency of the muscular coat (Simpson 1947, Carmichael 1950). Generally small, and often only a few millimetres in diameter, they may occasionally be large, reaching three or more centimetres across, but such large aneurysms, when they do occur, are more likely to cause symptoms by compressing neighbouring structures than by causing cerebral hæmorrhage. Intracranial aneurysms have certain sites of predilection, and these are well shown in fig. 1. They occur most frequently in the anterior half of the circle

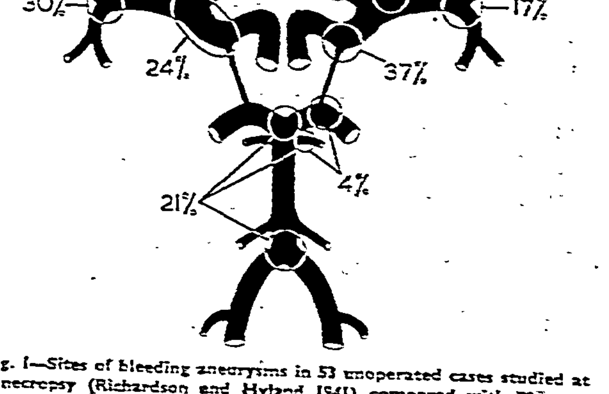

Fig. 1—Sites of bleeding aneurysms in 53 unoperated cases studied at necropsy (Richardson and Hyland 1941) compared with 70 cases operated on by the author.

---

* Fifth Alex Simpson Smith Memorial Lecture delivered at the West London Hospital Medical School on June 19, 1952.

of Willis, sometimes on arterial branches distal to the circle, notably the anterior cerebral artery and the middle cerebral artery, and only occasionally on the posterior half of the circle or on the basilar arterial system. These facts have *important bearings* :

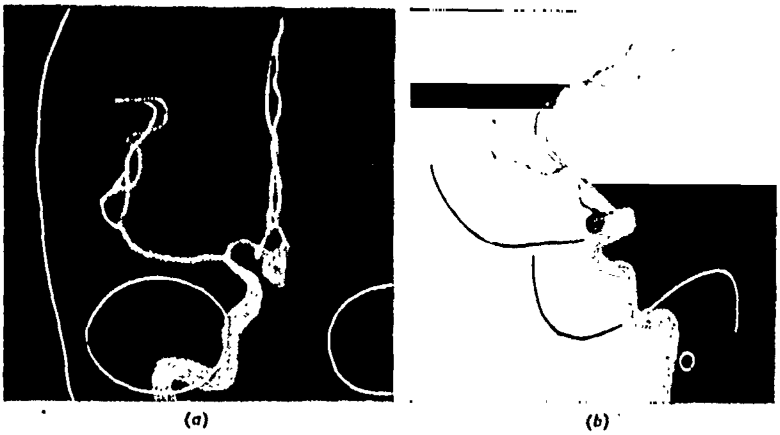
(1) Most intracranial aneurysms, particularly those which rupture, are supplied by the internal carotid artery and consequently can be demonstrated by carotid arteriography, whereas only a few aneurysms are so situated that vertebral arteriography is required to demonstrate them.

(2) Whereas aneurysms of the circle of Willis lie within basal cisterns and so bleed primarily into the subarachnoid space, aneurysms of the anterior cerebral artery distal to the circle and also of the middle cerebral artery tend to be surrounded by brain tissue and consequently on rupture produce a primary intracerebral hæmorrhage, which may only *secondarily* burst into a ventricular cavity or the subarachnoid space. Indeed, in the event of death, the pathologist, unless he carefully dissects out the distal cerebral arteries, may not find the causal aneurysm and may mistakenly label the case as one of idiopathic apoplexy.

(3) Aneurysms on the intracranial internal carotid artery—e.g., those situated in relation to the posterior communicating artery—may lie astride the arachnoid mater and can thus bleed into the subdural space, producing a subdural hæmatoma (Logue 1951, also my personal observations).

(4) Anomalies of the circle of Willis are often associated with intracranial aneurysms, perhaps in as much as a third of cases (personal observations), and these often have to be considered when planning surgical intervention.

Arteriovenous malformations have been described under different labels, of which cirsoid angiomas, arteriovenous aneurysms, arteriovenous hamartomas, and angiomatous malformations have each had wide acceptance. The lesion consists of a mass of coiled vessels, some arterial and some venous, which is fed by one or more large branches direct from a major cerebral artery and is drained by several large venous channels which each pass to a major venous sinus. The malformation may vary in diameter up to 10 cm. or even more and is essentially an arteriovenous fistula, the degree of shunting of arterial blood into the venous system sometimes being such as to influence adversely the circulation of blood through neighbouring parts of the brain. Some of these lesions are situated over the convexity of a cerebral hemisphere, others are deeply placed. Although of congenital origin (Olivecrona and Riives 1948), they gradually but steadily increase in size. Rarely do they produce symptoms before the age of 10 years. Epilepsy is then the common symptom, particularly with the larger malformations, but sometimes, especially with the smaller lesions, bleeding may occur instead. Such bleeding is generally intracerebral, but often it shortly spills into the subarachnoid fluid. There is a distinct tendency for the bleeding to be limited in amount but recurrent, so that several attacks may occur over the years before a fatal episode is reached (Wechsler and Gross 1948).

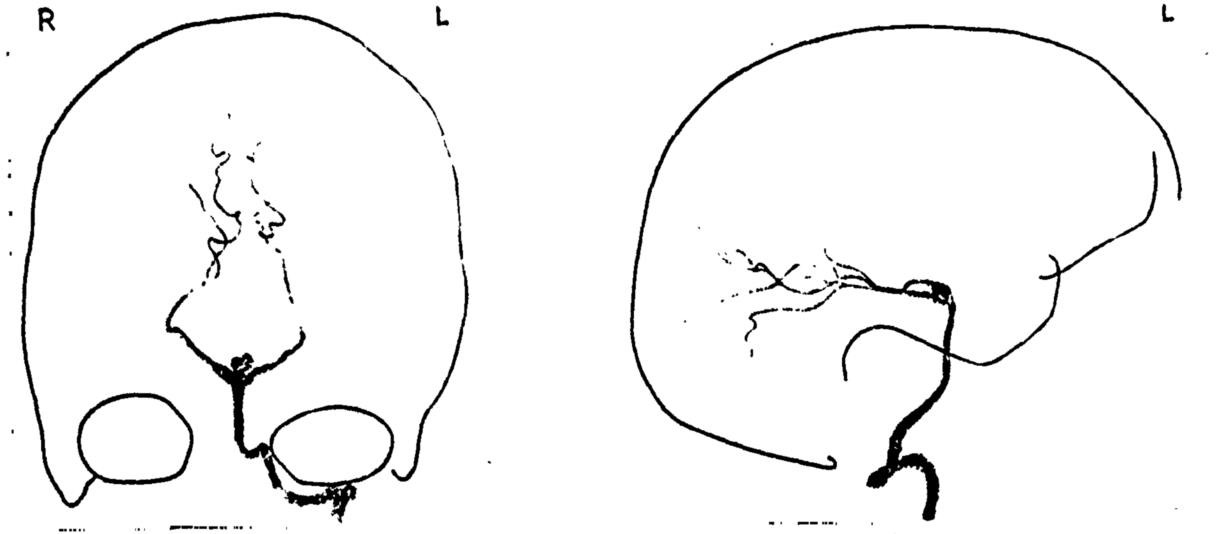


(a) (b)

Fig. 2—Tracings of carotid arteriograms showing aneurysm of anterior communicating artery. Both anterior cerebral arteries distal to this level are being filled. Treatment recommended : direct operative approach with possibly packing of aneurysm with muscle pledgets.

RECOGNITION OF CAUSES DURING LIFE

Most aneurysms and angiomas can be identified and located during life by cerebral arteriography (figs. 2 and 3), and the question therefore arises what are the indications and contra-indications for this procedure. The development by the Scandinavians (Lindgren 1947) during the 1939–45 war of a technique involving needle puncture of the carotid artery through the intact skin (percutaneous carotid arteriography) and the supersession



(a) (b)

Fig. 3—Tracings of left vertebral arteriograms showing aneurysm at bifurcation of basilar artery. Treatment recommended : ligation of left vertebral artery.

of ‘ Thorotrast ’ as the contrast medium by the excretable diodone solutions have made this investigation widely applicable. Indeed in expert hands percutaneous carotid arteriography has become safe and satisfactory, and can be readily used in most cases of recent cerebral hæmorrhage with little fear of upsetting the patient. It has, however, some important contra-indications. One of these is arterial hypertension with advanced vascular degeneration, for in such patients the introduction into an artery of even a slightly irritant medium may provoke vasospastic and thrombotic effects. Consequently it is not yet applicable to the large group of cases of internal capsular or pontine hæmorrhage occurring in hypertensive persons, which anyway, as stated earlier, is a group that is outside the scope and possibilities of surgery. In most cases of primary subarachnoid hæmorrhage, however, whatever the age-period, and in many cases of primary intracerebral hæmorrhage, especially in young or middle-aged persons, there is no such objection to the procedure. Our practice in such cases is to recommend that carotid arteriography be done early, preferably within a week of the onset of symptoms, so that the causal lesion may be recognised and its treatment begun before risk of recurrent bleeding rises to its peak. Mount (1951) in the United States and Norlén (1952) in Sweden make similar recommendations. Even in elderly and middle-aged people with subarachnoid hæmorrhage and a blood-pressure about 200/140 mm. Hg we would do percutaneous arteriography if the cardiovascular system otherwise seemed healthy, for in many such patients a bleeding intracranial aneurysm is responsible for the symptoms. We have noted that, when the acute symptoms subside, the blood-pressure sometimes returns to normal.

Our routine is to obtain in all cases of subarachnoid hæmorrhage bilateral carotid arteriograms, because in more than 10% of cases two or more aneurysms are present. Bilateral carotid arteriography is also useful in demonstrating the effectiveness of the collateral circulation of the circle of Willis; for, if the carotid of one side is compressed while that of the other is being injected, the contrast medium can often be demonstrated to pass across the midline to the opposite cerebral hemisphere. If carotid arteriography is negative, we usually proceed a few days later to vertebral arteriography (fig. 3), for which several techniques are available (Takahashi 1940, King 1942, Radner 1951). In these ways we feel that we can demonstrate most intracranial aneurysms or arteriovenous malformations. We can also deduce the presence of any sizable intracerebral or subdural clots adjacent to these lesions, and now and then we have located an intracerebral clot due to some other cause, such as a perforation of a cerebral vessel or the presence of a vascular tumour. The treatment of these various lesions now requires our attention.

TREATMENT OF BLEEDING INTRACRANIAL ANEURYSMS

Proximal Ligation

The sheet-anchor of treatment in intracranial aneurysms is ligation of either a carotid or a vertebral artery. Carotid ligation acts by reducing the arterial pressure within the aneurysm, so favouring its shrinkage or even its thrombosis. Always a somewhat risky procedure, in the presence of recent intracranial bleeding it seems to carry increased hazards. Schorstein (1940), for instance, reported a mortality-rate of 14% in 22 non-bleeding cases of aneurysm treated by carotid ligation, whereas in a comparable group of bleeding aneurysms the mortality was 55%. Jefferson (1952) and Johnson (1952) report having treated by carotid ligation 142 cases of aneurysm, both bleeding and non-bleeding, with only 12 deaths (mortality-rate 8%), but these deaths all occurred in a subgroup of 29 cases in which the carotid was ligated within a few hours of a severe hæmorrhage (mortality-rate in the presence of active bleeding 41%). Presumably in such cases the intracranial bleeding either kills by producing a large space-occupying lesion or it renders the brain more susceptible to anoxic effects of a partial diminution in the cerebral blood-supply, which otherwise would have been tolerated.

Several techniques of ligation have been tried in attempts to eliminate the risks of carotid ligation, but no one method has proved its superiority. There is, however, general agreement that ligation of a common carotid artery carries less risks than does ligation of an internal carotid artery. My own preference is to ligate the common carotid artery in two stages, and then the internal carotid artery in a further stage. Various precautions have usually to be taken beforehand to ensure that the ligation would be tolerated (Falconer 1950, 1951), and after these in 36 cases, nearly all of recent bleeding, I experienced a mortality of 17%.

Ligation of one vertebral artery, that artery being selected which had been successfully filled on arteriography, has now been done by me in three cases of aneurysm of the basilar or of the posterior cerebral artery. In each instance the artery was exposed under local analgesia at its origin low in the neck, and was only tied after a trial period of occlusion had been tolerated. All three patients recovered, but it is difficult to judge the merits of the procedure from so few cases. Although Dandy (1944) stated that he had ligated one vertebral artery “perhaps 20 times without any untoward effect,” the procedure has risks, and fatalities following ligation of one vertebral artery have been reported by Guthkelch (1949) and by French and Haines (1950). Moreover its efficiency is diminished by the fact that the other vertebral artery remains patent and will still supply the arterial segment which carries the aneurysm.

Intracranial Approach

Carotid ligation by itself is of great value for aneurysms of the internal carotid artery, but for aneurysms on the circle of Willis or its distal arterial branches its benefits may be only transient because of the collateral circulation from the opposite carotid artery through the circle of Willis. Several surgeons (Falconer 1951, Mount 1951, Norlén 1952) therefore recommend that most aneurysms should be tackled by a direct operative approach along the lines advocated by Dandy (1944). By means of a frontal craniotomy it is generally possible to expose an aneurysm of the internal carotid artery or of the anterior or middle cerebral arteries without damaging or sacrificing any cerebral substance. The intracranial internal carotid artery and its bifurcation are readily exposed by a subfrontal approach, the anterior cerebral artery by retracting the frontal lobe from off the falx and the opposite cerebral hemisphere, and the middle cerebral artery by opening up the fissure of Sylvius. Any sizable clots from within the adjacent frontal or temporal lobes should be removed so that their space-occupying effects can be relieved. Such intracerebral clots occur particularly with aneurysms of the anterior and middle cerebral arteries.

Once an aneurysm is exposed, various local measures can be applied to it according to circumstances. Its neck, if narrow and accessible, can be clipped or ligated with silk. If the collateral circulation is adequate, the parent artery can be clipped or ligated on either side of the aneurysm, thus trapping it. Now and then the aneurysm may be excised, as when it is situated on a relatively unimportant vessel, such as the distal part of the anterior cerebral artery. The method which I have found most generally applicable is to wrap pledgets of hammered muscle round the aneurysm, after its sac has been carefully freed on all sides. This method, first introduced by Dott (1933), seems in my experience to be of permanent value. It does not impair the flow of blood through the diverging parent arteries, and thus has particular merit when the aneurysmal neck is inaccessible or is too wide to carry a clip or a ligature. Occasionally one encounters an aneurysm which is too large to be treated in any of these ways, and can be treated only by proximal arterial—e.g., carotid—ligation.

One of the risks in exposing an intracranial aneurysm is that it may burst while it is being dissected out. This has happened to me several times, but fortunately I have always managed to control the bleeding by packing the aneurysm round with hammered muscle. This complication, however, can be obviated through lowering the blood-pressure during operation by producing a postural hypotension with the hexamethonium drugs (Enderby 1951). The method has its hazards, but the secret seems to be not to lower the systolic blood-pressure in the brachial artery, where it is normally recorded, too far—e.g., below 80-90 mm. Hg—for the intracranial arterial pressure may be even less than this, especially when the head is postured a little above the rest of the body. In an early stage of our experience we lowered the blood-pressure to 60-70 mm. (a level advocated for some other fields of surgery) and in one patient we encountered an alarming cessation of respiration. Further experience is necessary before we become acquainted with all the major hazards of this refinement of anæsthesia, but the method holds much promise.

By March, 1952, I had operated on 70 cases of intracranial aneurysm, mostly with recent bleeding: 47 patients have made a good recovery, 11 have been left with a residual disability, and 12 have died in the postoperative period (mortality-rate 17%). One death, however, was from paroxysmal tachycardia and disease of the coronary artery. Nine of the deaths were in a subgroup of 57 patients submitted to an intracranial operation, often after a preliminary carotid ligation (mortality-rate 21%). The remainder were treated by proximal arterial ligation. These results are a great improvement on the prospects of patients treated conservatively, and probably most of the patients who survived will prove to have permanently recovered. But the chance of later rupture from a second aneurysm remains. My cases have now been followed up for periods of up to six years. The follow-up is fairly complete, and I have learnt of 2 deaths occurring two or three years after operation. In each instance a necropsy revealed a second and untreated intracranial aneurysm which had ruptured.

TREATMENT OF BLEEDING ARTERIOVENOUS MALFORMATIONS

Until recently these lesions were regarded as rare and hopeless propositions. Attempts at treating them were limited to either carotid ligation or to deep X-ray therapy. There was never any good evidence that either procedure conferred benefit. Carotid ligation could even be dangerous, as Olivecrona (1944) learnt when hemiplegia supervened in 4 of 7 cases in which he applied this treatment, the hemiplegia proving permanent in 2 cases in which the ligature was not removed. The explanation probably is that the short-circuiting of blood through the fistula heightens the risk of severe anoxæmia of the affected hemisphere when the total blood-supply to the brain is diminished by tying off one carotid artery. Olivecrona and Riives (1948) reported having observed a continued increase in the size of the malformation in a case which was treated intensively by deep X-ray therapy.

As a result of the more frequent use of cerebral arteriography (fig. 4) we now know that these lesions are much more common than was hitherto thought. We also know that most of them are directly operable, preferably by complete excision or, if that is not practicable, by clipping of the feeding arteries. The technique of excising these lesions was worked out particularly by the Swedish neurosurgeons (Olivecrona and Riives 1948, Norlén 1949) and is readily applicable if the lesion is accessible, as when it is situated over the convexity of the cerebral hemisphere. Any associated intracerebral clot is, of course, removed. Sometimes, however, the malformation is deep-seated or is situated in a particularly eloquent region, such as Broca's area, and then excision of the lesion may be either impossible or fraught with grave risks of maiming. In such circumstances surgical intervention is limited to evacuation of the clot plus ligation or clipping of the arterial branches which feed the malformation (Jaeger 1950). Even this simpler measure will usually render the malformation impotent as regards further bleeding, and in postoperative arteriograms the arteries in other regions of the cerebral hemisphere will be seen to fill more normally because the arteriovenous shunt has been corrected (personal observations).

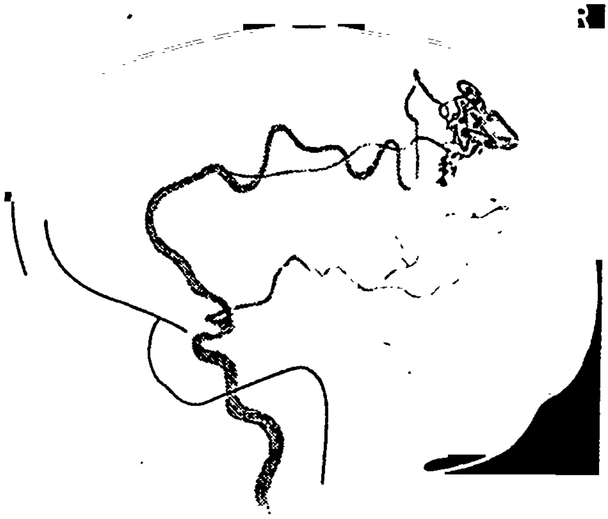


Fig. 4—Tracing of carotid arteriogram showing arteriovenous malformation at termination of anterior cerebral artery. Treatment recommended: excision.

My own experience of bleeding arteriovenous malformations now extends to 9 cases, of which 3 were excised, 1 was treated only by evacuation of the clot, and the remainder were treated by clipping the feeding arteries. All the patients recovered after craniotomy. The 3 malformations which were excised were all cortical lesions situated close to the superior longitudinal fissure; all 3 lesions had bled intracerebrally, and subsequently each patient was left with a mild permanent monoplegia attributable to such bleeding. Two other cortical malformations, both small but situated on the upper lip of the Sylvian fissure in the dominant hemisphere, were treated by clipping of the feeding arterial branches with almost no residual disability. Three further cases all had lesions deep-seated on a posterior cerebral artery, and in 2 of these the lesion appeared to be situated within the trigone of a lateral ventricle. All were treated by clipping of the posterior cerebral artery as it wound backwards and lateral to the crus cerebri, and just anterior to the point at which the artery gave off its posterior choroidal branch. The necessary access in each instance was obtained by lateral craniotomy with elevation of the temporal lobe from off the middle cranial fossa. In 2 of 3 patients this procedure was followed by a permanent homonymous hemianopia, but not in the third. My remaining case was in a child, aged 3 years, from whom I evacuated an intracerebral clot which had caused symptoms of semicoma and vomiting lasting a few days. At operation a small arteriovenous malformation was seen in the adjacent brain. This was several years ago, before my present interest in these lesions; but, so far as I know, the child still survives. My personal experience therefore is that bleeding arteriovenous malformations, whether superficial or deep, can usually be dealt with by surgery.

TREATMENT OF SPONTANEOUS PRIMARY INTRACEREBRAL HÆMORRHAGE

Spontaneous intracerebral hæmorrhage from causes other than aneurysm and arteriovenous malformation is a field which is awaiting developments in surgery. Overshadowing the field is the grim spectre of the type of intracerebral hæmorrhage which so often terminates the life of hypertensive and arteriosclerotic people. Such hæmorrhages are usually deep-seated, often in the basal ganglia or internal capsule, are usually rapidly fatal, and offer surgery no prospects, because the lesion is inaccessible and extensive damage is usually caused to deep structures in the brain. Rose (1948) has shown that 80% of such patients die within 2–24 hours of the onset of symptoms. Fortunately not all cases of arteriosclerotic bleeding follow this pattern, and there are also other causes of primary intracerebral hæmorrhage which are favourable for surgical treatment (Penfield 1933, Craig and Adson 1936, Beck 1952).

The following four personal case-records indicate something of the surgical possibilities. Bleeding presumably took place from an arteriosclerotic artery in a hypertensive person in case 1, from an obscure arterial perforation in a child in case 2, and from metastatic tumour with an apparently favourable prognosis in case 3; and no cause for the bleeding was found in case 4.

Case 1.—A man, aged 56, suddenly found, while driving his car, that he could not see the left-hand side of the road, and shortly afterwards developed a severe headache. That night he became drowsy and confused, vomiting frequently. When examined three days later he exhibited a left-sided hemiparesis and a left homonymous hemianopia. His blood-pressure was 180/110 mm. Hg. His C.S.F. was xanthochromic. Right carotid arteriography disclosed displacement upwards and forwards of the right middle cerebral artery, indicating a large space-occupying lesion within the parietal lobe. At operation a large amount of dark clotted blood was evacuated from within that lobe. No source of bleeding was seen. The patient subsequently recovered, but hemianopia persisted.

Case 2.—A boy, aged 9 years, suddenly slumped across his desk in class. He rallied shortly afterwards but became unconscious again within twenty-four hours. When admitted to a neurosurgical unit on the second day he responded only to painful stimuli. Neck retraction, opisthotonos, and right hemiparesis were present. The C.S.F. was much bloodstained. Bilateral carotid arteriography showed considerable displacement of both anterior cerebral arteries to the right side, with depression of the left middle cerebral artery. At operation a massive clot was evacuated from within the left frontal lobe. Inspection showed a tiny intramural hæmorrhage in the left anterior cerebral artery close to its origin. This was evidently a tiny perforation, and seemingly had been the site of bleeding. The boy recovered completely.

Case 3.—A man, aged 46, suddenly developed headache with vomiting, and during the next few days became increasingly drowsy and confused. When admitted six days later he was stuporose and exhibited bilateral papillœdema, scanty localising signs, and xanthochromic C.S.F. Ventriculography indicated a right temporal space-occupying lesion. At operation this proved to be an intracerebral clot surrounding a small tumour, which was removed and proved to be a metastatic hypernephroma. Renal investigations, including a unilateral kidney exploration, revealed no abnormality. The patient remains symptom-free eight years later.

Case 4.—A girl, aged 12 years, but not yet menstruating, had complained, for more than three months, of morning headaches with occasional vomiting. There was no history of trauma. The symptoms seemed to be gradually increasing. Examination disclosed bilateral papillœdema and an incomplete right homonymous hemianopia as the only neurological signs. At operation an encapsulated hæmatoma containing solid clot was found. The source of the bleeding was not seen. Postoperative carotid and vertebral arteriograms showed no abnormality. The patient recovered completely.

Such case-histories could be multiplied by the experience of other workers (Penfield 1933, Craig and Adson 1936, Beck 1952). Primary intracerebral hæmorrhage can occur at all ages. Bleeding aneurysms, arteriovenous malformations, trauma, and unsuspected tumours account for some cases, but often no source of bleeding can be found. Presumably in some of these cases leakage from a degenerate artery is responsible for the bleeding, but in others there is no evidence of widespread arterial disease. As regards the mode of presentation, those intracerebral hæmorrhages which have surgical possibilities may present one of two patterns (Craig and Adson 1936, and my own observations). In the usual pattern the onset is abrupt, but instead of succumbing rapidly the patient shortly afterwards begins to revive, presumably because active bleeding has ceased. The patient then presents signs of focal cerebral damage, such as a monoplegia or a hemianopia, but in contrast to the deep-seated capsular hæmorrhages the hemiplegia is seldom complete. In cases which conform to this pattern a diagnosis of cerebral vascular accident offers no difficulties. In the second pattern, however, the appearance of symptoms is gradual and progressive, suggesting a brain tumour. Case 4 was an example of this. Such cases will, of course, continue to be regarded as neoplasms until the true nature of the lesion is disclosed at operation. They are, however, less common than cases presenting the first pattern.

The inference from these various observations is that every patient whose history strongly suggests a primary intracerebral hæmorrhage, who does not succumb shortly after the onset, and who is not grossly hypertensive, should be investigated by carotid arteriography. If such a rule were followed, many more cases of intracerebral hæmorrhage suitable for operation would be recognised.

THE FUTURE

Surgery thus has much to offer for the treatment of most varieties of spontaneous cerebral hæmorrhage. In the development of this field Dott (1933) and Jefferson (1937) in this country, Moniz (1934), Krayenbühl (1941), and Olivecrona (1944) on the Continent, and Dandy (1944) in the United States must be regarded as the chief pioneers, but many others have also contributed. Mount (1951) has collected statistics relating to the mortality of subarachnoid hæmorrhage and has shown that in 752 medically treated cases, comprising his own as well as seven large series previously published, there was a mortality-rate of 48%. On the other hand, in 469 surgically treated cases from thirty-seven sources, also published, there was a mortality of 14%. Although there may be objections to a strict comparison of these two groups, these findings clearly show that the prognosis of subarachnoid hæmorrhage can be greatly improved by timely surgical intervention.

Surgery in these conditions is still in its early stages, and we have a great deal yet to learn about the handling of these various lesions. Without doubt there will be many more advances. The statistics of the Registrar-General show that in 1949 the crude death-rate in England and Wales for cerebral hæmorrhage was 737 cases per million living persons and for subarachnoid hæmorrhage 30 cases per million. (Comparable figures for cerebral embolism and thrombosis were 536 deaths per million living persons [Registrar-General, personal communication].) The scope for surgery is thus large, for cerebral hæmorrhage is the principal killing disease of the nervous system, and many of these deaths undoubtedly could be prevented. The time may well come when our neurosurgical units find that the number of patient, referred to them with these conditions surpasses the number referred with brain tumour.

I am grateful to Miss S. Treadgold and Miss M. J. Waldron, of the department of medical illustration, Guy's Hospital, for the illustrations.

OBSTETRIC SURGEON, GUY'S HOSPITAL; SURGEON, CHELSEA HOSPITAL FOR WOMEN AND QUEEN CHARLOTTE'S MATERNITY HOSPITAL, LONDON

IN 1944 a joint clinic was set up between the Chelsea Hospital for Women and the Royal Cancer Hospital for the treatment of cancer patients requiring radiotherapy. The organisation of the clinic is simple: a cancer reference clinic is held once a week at the Chelsea Hospital for Women; a surgeon appointed by the Chelsea Hospital for Women (J. B. B.) and a radiotherapist appointed by the Royal Cancer Hospital (M. L.) conduct the clinic together. Patients with cancer may be referred directly to the clinic, or the radiotherapist may see a case with one of the members of the staff of the Chelsea Hospital for Women; in either event, decisions about treatment are taken jointly by surgeon and radiotherapist. Where radiotherapy is agreed upon the patient is transferred to the Royal Cancer Hospital and undergoes examination under anæsthesia, biopsy, and cystoscopy.

TABLE I—PATIENTS SEEN IN 1944–46

—	1944	1945	1946	Total
No. of cases seen:	48	41	50	139
No. previously untreated	46	37	50	133
No. previously treated (recurrent)	2	4	0	6
No. treated	46	39	46	131
No. not treated	2	2	4	8

TABLE II—AGE-DISTRIBUTION OF PATIENTS IN 1944–46

—	Age of patients (yr.)						Total
	30–	40–	50–	60–	70–	80–	
No. of cases	12 *(9%)*	35 *(25%)*	42 *(30%)*	38 *(27%)*	9 *(7%)*	3 *(2%)*	139

In most cases decisions about the precise form radiation treatment should take are readily reached when the patient is first seen; in difficult cases, however, decisions of this sort are taken only after an examination under anæsthesia. It is an invariable rule that final decisions are only taken after full consultation between the surgeon and the radiotherapist conducting the clinic, and repeated consultations are held throughout the course of treatment. In this way the radiotherapist has the help of the surgeon on clinical matters, and the surgeon has the help of the radiotherapist in the complicated technique of radiotherapy.

TABLE III—HISTOLOGY OF TUMOURS 1944–46

—	No. of cases
Squamous-cell carcinoma	108 *(78·0%)*
Adenocarcinoma	11 *(8·0%)*
Anaplastic carcinoma	5 *(3·5%)*
No biopsy	15 *(10·5%)*
Total	139

From the point of view of technical approach, the patients in stages I and II are usually treated first by radium and in nearly all cases receive post-radium X-ray therapy. Patients in stages III and IV receive X-ray therapy first and a modified radium treatment thereafter. The planning of the X-ray treatment and the technical details of the radium treatment are entirely the responsibility of the radiotherapist, whereas the insertion of radium is largely the work of the gynæcological surgeon, the radiotherapist deputising for him when necessary. When large numbers of patients have to be treated, the insertions are shared so that the risks of exposure to each operator may thereby be lessened. The radium technique used is a modified Stockholm method. Three

TABLE IV—DISTRIBUTION OF PREVIOUSLY UNTREATED CASES ACCORDING TO STAGE AND RESULTS OF TREATMENT FOR 1944–46

—	Stage I	Stage II	Stage III	Stage IV	Total
No. of cases seen	32 *(24%)*	60 *(45%)*	33 *(25%)*	8 *(6%)*	133
No. of cases treated	32	57	32	4	125
No. of cases not treated:	0	3	1	4	8
No. refusing treatment	0	3	1	0	4
No. too advanced for treatment	0	0	0	4	4
No. of patients alive and well 5 years after treatment:	17	*27*	*5*	*0*	49
Cure-rate of cases seen	53%	45%	15%	0	37%
Cure-rate of cases treated	53%	47%	16%	0	39%
No. of patients not traced (counted as dead of disease)	0	1	0	0	1
No. of patients dead of intercurrent disease	3	2	1	0	6

insertions of radium are made, each for twenty-two hours, at intervals of a week between the first and second insertions and two weeks between the second and third insertions. The total amount of radium used is 50–60 mg. in the uterus and 30–75 mg. in the vaginal vault. For the X-ray treatment a 400 kV apparatus is used. Two main techniques are used depending on whether the radium treatment is given before or after the X-ray treatment.

Table I shows the number of cases seen in 1944–46, table II gives the age-distribution of the patients forming the series, and table III the histological types of tumours seen. Of the 15 patients in table III without histological confirmation 13 died of cancer of the cervix within five years and only 2 patients, both in stage II, are alive and well without histological confirmation. Table IV shows the distribution of the material according to stage and the results of treatment according to stage (classification according to League of Nations method of staging 1950).

TABLE V—METHOD OF TREATMENT OF PREVIOUSLY UNTREATED CASES

—	1944	1945	1946	Total
No. of cases treated by radiotherapy	36	25	41	102
No. of cases treated by Wertheim's hysterectomy	4	9	3	16
No. of cases treated by other methods	4	1	2	7

Table V shows the different methods by which the previously untreated cases were subsequently treated. The bulk of the patients were treated by radiotherapy, Wertheim's hysterectomy being used only occasionally. The decision to treat the patients by Wertheim or "other methods" was usually made by the surgeon in charge of the case.

TABLE VI—RESULTS OBTAINED WITH TREATMENT BY RADIOTHERAPY 1944–46

—	Stage I	Stage II	Stage III	Stage IV	Total
No. of cases treated	19 (*19%*)	49 (*48%*)	30 (*29%*)	4 (*4%*)	102
No. of patients alive and well 5 years after treatment ..	9 (*47%*)	25 (*51%*)	4 (*13%*)	0	38 (*37%*)
No. of patients not traced ..	0	0	0	0	0
No. of patients dead of intercurrent disease	3	2	1	0	6
No. of patients alive and well 5 years after treatment expressed as percentage of no. treated, excluding no. dead of intercurrent disease ..	56%	53%	14%	0	40%

Table VI gives the results obtained by radiotherapy. Apart from the stage I cases, the results obtained compare well with those obtained at other centres. The reasons for the unsatisfactory stage I results we believe to be the statistically insignificant number of cases, and the fact that 6 of the 19 patients received their radium treatment at the Chelsea Hospital for Women without reference to the radiotherapist. Of these 6 patients 4 died of recurrent disease. Of the 13 patients referred via the Cancer Clinic and treated at the Royal Cancer Hospital 3 died of cancer, 3 died of intercurrent disease, and the remaining 7 are alive and well.

TABLE VII—RESULTS OBTAINED BY WERTHEIM'S HYSTERECTOMY 1944–46

—	Stage I	Stage II	Stage III	Total
No. of cases treated ..	11	4	1	16
No. of patients alive and well 5 years after treatment	7	1	1	9 (*56%*)
No. of patients not traced	0	0	0	0
No. of patients dead of intercurrent disease ..	0	0	0	0

TABLE VIII—RESULTS OBTAINED WITH TREATMENT OTHER THAN RADIOTHERAPY OR WERTHEIM'S HYSTERECTOMY

—	Stage I	Stage II	Stage III	Total
No. of cases treated	3	3	1	7
No. of patients alive and well 5 years after treatment ..	1	1	0	2
No. of patients not traced ..	0	1	0	1
No. of patients dead of intercurrent disease	0	0	0	0

It is our conviction that, for radiotherapy to be successful, it must be given under proper conditions by people thoroughly experienced in the method.

TABLE IX—RESULTS OBTAINED BY RADIOTHERAPY AT CHELSEA HOSPITAL FOR WOMEN 1936–43

—	Stage I	Stage II	Stage III	Stage IV	Total
No. of cases treated	52 (*15%*)	116 (*34%*)	147 (*43%*)	29 (*8%*)	344
No. of patients alive and well 5 years after treatment ..	20 (*39%*)	32 (*28%*)	22 (*15%*)	1 (*3%*)	75 (*22%*)
No. of patients not traced (counted as dead of cancer)	6	10	12	1	29

Table VII gives the results obtained with surgical treatment. The numbers are too few to be statistically valid, but one can safely form the opinion that the radotherapy results compare more than favourably.

In table VIII are collected 7 cases treated by means other than radiotherapy or Wertheim's hysterectomy. Three of these cases had already been treated inadequately before the diagnosis was made, and in the remaining 4 cases an attempt at Wertheim's operation was abandoned, owing to technical difficulties, and radiation treatment was given. If these 4 cases are included with those on whom the operation was completed, the cure-rate is 50%, and not 56%, for cases treated by Wertheim's hysterectomy.

The advantage to those patients with cancer of the cervix who attend the cancer clinic at the Chelsea Hospital for Women is shown by comparing table VI with table IX. The latter table gives the results obtained by radiotherapy at the Chelsea Hospital for Women for the years 1936–43 before the joint clinic with the Royal Cancer Hospital was set up. For comparison the results obtained by Wertheim's hysterectomy over the same period are given in table X.

TABLE X—RESULTS OBTAINED WITH TREATMENT BY WERTHEIM'S HYSTERECTOMY AT CHELSEA HOSPITAL FOR WOMEN 1936–43

—	Stage I	Stage II	Stage III	Total
No. of cases treated	43 (*60%*)	26 (*37%*)	2 (*3%*)	71
No. of patients alive and well 5 years after treatment	19 (*44%*)	11 (*42%*)	0	30 (*42%*)
No. of patients not traced	6	3	0	9

We are indebted to our surgical colleagues on the staff of the Chelsea Hospital for Women for referring cases to us and for their coöperation and encouragement.

THE REVERSIBILITY OF MALIGNANT HYPERTENSION

G. W. Pickering
M.A., M.B. Camb., M.D. Ghent., F.R.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF LONDON

A. Dickson Wright

With illustrations on plate

Volhard and Fahr (1914) were the first to point out that essential hypertension might behave in one of two ways. In most patients the course of the disease was long, the patient's condition showing little change year by year, and death, when at length it came, being due to heart-failure, to apoplexy, or to intercurrent disease. This they named the benign form. In a few patients, usually younger, the disease followed a rapidly fatal course. The onset of this form, which they named malignant hypertension, was heralded by the appearance of albuminuric retinitis, soon followed by albumin and red cells in the urine and by progressive renal failure terminating in uræmia, usually within a year from the first appearance of retinitis.

Volhard showed that the distinctive clinical feature of malignant hypertension is albuminuric retinitis (hypertensive neuroretinopathy). This can be distinguished from arteriosclerotic retinitis (Foster Moore 1916–17) by the presence of bilateral neuroretinal œdema, which is absent in arteriosclerotic retinitis except as a local consequence of venous thrombosis. As Foster Moore showed, arteriosclerotic retinitis carries a much better prognosis, and it is found chiefly in benign hypotension.

Albuminuric and arteriosclerotic retinitis are, as a rule, easily distinguished, but they overlap; some cases present features of both, and one may pass into the other. Partly for this reason it is generally agreed that the most important distinction between malignant and benign hypertension is the presence in malignant hypertension, and the absence in benign hypertension, of acute arteriolar necroses (Fahr 1919). These necroses are most frequent and severe in the kidney, where they are presumably responsible for the onset and rapid progress of renal failure; they occur also in gut, pancreas, adrenal, eye, brain, heart, and liver, but not in skeletal muscle and skin.

Since Volhard and Fahr's original description it has become apparent that malignant hypertension is a syndrome that may occur in hypertension due to many causes. Ask-Upmark (1929) observed it in children with unilateral renal deformities; Klemperer and Otani (1931) in nephritis; and MacMahon et al. (1934) in Cushing's syndrome. Derow and Altschule (1935) gathered together these pieces of evidence, added more of their own, and suggested that malignant hypertension "is a syndrome which may occur (*a*) with no evidence of previously existing hypertension, (*b*) as the end stage of essential hypertension, (*c*) as the end stage of a miscellaneous group of conditions characterised by hypertension secondary to acute, subacute, or chronic glomerulonephritis, pyelonephritis, adrenal tumour, pituitary basophilism, periarteritis nodosa, hyperemesis gravidarum,* chronic lead poisoning, et cetera." In a later paper (Derow and Altschule 1941) they said that "the mechanism by which the benign course of primary or secondary hypertension is suddenly and dramatically transformed into the rapid progressive downhill course of the syndrome of malignant hypertension is not understood. Attempts to incriminate infectious toxins, mental stress, or other factors have been inconclusive."

In 1942 one of us (G. W. P.) put forward the hypothesis "that the benign and malignant courses of hypertension are merely expressive of the severity of the hypertensive process, irrespective of the lesion which ultimately determines it." It was suggested that, whatever the underlying disease, the course of the hypertension would be of the malignant type if the arterial pressure was sufficiently raised, and of the benign type if the rise was less. On this hypothesis the answer to Derow and Altschule's question would be that the benign is transformed to the malignant type of hypertension if the arterial pressure rises and is maintained above a certain critical level.

This hypothesis was based on two chance observations relating to the mechanisms by which the characteristic features of malignant hypertension are produced. It was observed that in albuminuric retinitis the pressure of the cerebrospinal fluid (C.S.F.) is nearly always above the level at which papillœdema occurs in tumour of the brain, whereas in arteriosclerotic retinitis the pressure of the C.S.F. is lower. The presence of neuroretinal œdema in the albuminuric but not in the arteriosclerotic form of retinitis can thus be accounted for by the level of C.S.F. pressure. The level of C.S.F. pressure seemed to be determined, at least in part, by the diastolic arterial pressure. And so the differences in the retinal lesions of malignant and benign hypertension seemed to be in part, at least, a consequence of the intensity of the hypertension (Pickering 1934).

Acute arteriolar necroses in hypertension following constriction of a renal artery in the dog were described by Goldblatt (1938) and in the rabbit by Wilson and Pickering (1938). These necroses were found in the same organs as in man, with the important exception that they were absent from the kidney whose artery had been clamped. Because of this, and because they were only found in animals with the highest arterial pressures, Wilson and Pickering attributed the lesions to a rise of intra-arterial pressure above a certain point.

Wilson and Byrom (1939) found that in the rat severe and persistent hypertension followed constriction of one renal artery, the other kidney being intact; in the early stages of hypertension the lesions were present in the kidney with the intact artery but not in the other kidney, whose artery had been clamped. These observations showed clearly that hypertension was the cause of the arteriolar necroses and of the renal lesions of malignant hypertension, which were shown to be identical in the unclamped kidney of the rat and in the kidneys of patients with malignant hypertension.

Though Wilson and Pickering had found in the rabbit that necroses occurred only in animals with greatly raised arterial pressures, Wilson and Byrom did not find any correlation between the presence or absence of arteriolar necroses and the level of the blood-pressure in the rat; but in the rabbit no anæsthetic was used, whereas the blood-pressure was measured in the rat under anæsthesia, which may itself influence arterial pressure.

Byrom and Dodson (1948) have shown that, if one renal artery is temporarily occluded by a ligature, and saline solution is injected forcefully through the carotid into the aorta so that the intra-aortic pressure is briefly and repeatedly raised by more than 80–90 mm. Hg, acute arteriolar necroses are found in the unprotected, but not in the protected, kidney three days later.

This experiment, though unphysiological, provides unequivocal evidence that acute arteriolar necroses can be produced by rise of pressure in the lumen above a certain point. Whether the necrosis is due to death of the tissues of the wall or merely to deposition in the wall of protein and, in some cases, cells from the blood is not accurately known.

---

* Nowadays presumably pre-eclamptic toxæmia would be substituted.

If this hypothesis concerning the nature of benign and malignant hypertension is correct, it follows that, if the arterial pressure can be reduced sufficiently and for long enough, albuminuric retinitis should disappear and arteriolar necroses cease to be produced; in short, the hypertensive disease should revert from the malignant to the benign form. There is already a great deal of evidence that treatments which produce a considerable and long-continued reduction in blood-pressure will cause albuminuric retinitis to disappear, and some evidence that they prolong life.

The evidence for relief of albuminuric retinitis by sympathectomy and other operations designed to reduce sympathetic vasomotor tone has been reviewed by Hollenhorst and Wagener (1949). That sympathectomy prolongs life in malignant hypertension has been shown by Woods and Peet (1941), Hammarström and Bechgaard (1950), and Smithwick (1951). Reduction in arterial pressure and resolution of albuminuric retinitis have also been produced by pyrogens (Page and Taylor 1949), restriction of sodium intake (Kempner 1948), and hexamethonium bromide (Smirk and Alstad 1951) in the malignant phase of essential hypertension, and by nephrectomy in unilateral pyelonephritis (Langley and Platt 1947, and case 1 in the present series).

Nevertheless, there has not yet been reported any case in which malignant hypertension, proved histologically, has been converted to the benign course. We therefore present the following three cases in which this evidence was obtained. All three cases were of pyelonephritis; all showed gross albuminuric retinitis with bilateral papillœdema and large exudates; and all showed typical acute arteriolar necroses in suprarenal glands and kidneys. All showed a fall of arterial pressure and resolution of albuminuric retinitis following operation, and now, five to six years later, all the patients are alive and subjectively well, with normal blood-urea levels and mild to severe hypertension.

THE FIRST CASE

A meter reader, aged 33, attended the Western Ophthalmic Hospital in December, 1945, with failing vision. He was found to have albuminuric retinitis, albuminuria, and an arterial pressure of 240/170 mm. Hg, and was referred to St. Mary's.

History

In 1932 he had a hæmoptysis and was treated with an artificial pneumothorax, first at the Brompton Hospital and subsequently at Frimley Sanatorium. In 1932 his left testicle, and in 1937 his right testicle, were removed for tuberculous orchitis. His father had died at the age of 69, two days after gastrectomy for stomach trouble; his mother had died twelve hours after a fit in which she became unconscious. He had four brothers and a sister alive and well. He had been well until November, 1945, when he began to get frontal headaches worst on waking and disappearing about midday, and failing vision first in the left and later in the right eye. He had no abnormalities of micturition.

Examination (Dec. 14, 1945)

He was a spare man with fine hair and thin skin and no beard or axillary hair. The cardiac impulse was 4½ in. from the midline in the fifth space, and the second sound was loud. The arterial pressure was 226/148. No masses were felt in the abdomen. The fundus showed bilateral papillœdema with large woolly exudates and a macular star figure on both sides (fig. 1). The arteries were rather small and the veins rather full.

Condition on Admission

When he was admitted to hospital under Dr. Thomas Hunt on Feb. 5, 1946, the clinical findings were essentially the same. The blood-urea was 37 mg. per 100 ml., and urea concentration to 2·6%. Examination of a twenty-four-hour specimen of urine on two occasions showed no tubercle bacilli. Intravenous pyelography showed a non-excreting right kidney.

Operation (Feb. 25 1946)

The right splanchnic nerves, the right 1st and 2nd lumbar ganglia, the right adrenal, and the right kidney were removed. The arterial pressure (fig. 2) fell precipitously after operation, subsequently settling to 150–170 systolic and 100–120 diastolic, at which level it was maintained for the next six years.

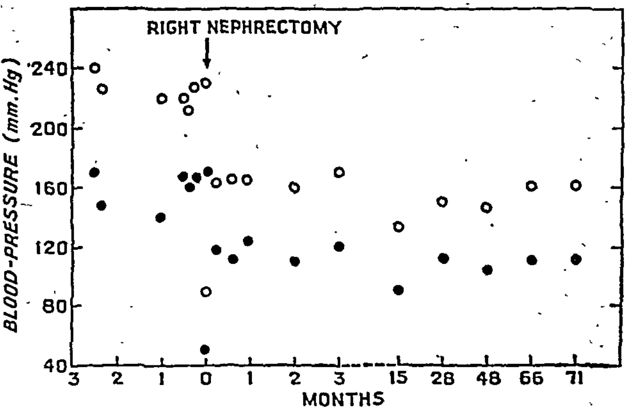

Fig. 2—Case 1: course of arterial pressure.

Progress

The blood-urea was 30 mg. per 100 ml. on March 14, 1946, and urea concentration to 3·6% the next day and to 2·7% on Sept. 25, 1947. The fundus cleared rapidly (fig. 3). A month after operation the papillœdema had gone and the woolly exudates had resolved completely or become small and sharply defined. At two months the exudates had gone, but the star figure was unchanged. The star figures slowly resolved during the fifteen months following operation (fig. 4).

In February, 1950, he had a hæmatemesis. Three weeks later a barium meal showed a duodenal ulcer. Blood-pressure 145/105. Fundi: no papillœdema or exudates.

On Aug. 22, 1951, he was very well and at work. Blood-pressure 160/110. Fundi: no papillœdema or exudates. Urine: no albumin, no excess of cells. Blood-urea 38 mg. per 100 ml.

On Jan. 18, 1952, he was well. Blood-pressure 160/110. Blood-urea 36 mg. per 100 ml. Fundi normal. Urine: no albumin or excess of cells.

On March 14, 1952, he was well. Blood-pressure 175/120.

Operation Specimens

Right kidney.—This measured 7·0 × 4·0 × 2·5 cm. Its surface was coarsely nodular, and on section the parenchyma appeared reduced in width, especially in the areas corresponding to the scars. The pelvis and calyces were dilated, and the pelvic wall was thickened.

Histologically the general picture was of chronic pyelonephritis, the affected areas showing interstitial fibrosis, lymphocytic infiltration, and reduction of the glomeruli. The tubules were lined with atrophic epithelium and contained deeply eosinophil casts. The pelvis was thickened with fibrous tissue and numerous lymphocytes were present beneath the epithelium. Relatively normal areas of kidney tissue intervened between the scars.

In the scarred areas the arterioles were thickened, and some presented the picture of fibrinoid necrosis (fig. 5). In its fully developed form fibrinoid necrosis was characterised by a diffuse replacement of the vessel wall by deeply eosinophil granular material closely resembling fibrin. This imparted a smudgy appearance to the vessel wall, and nuclear structure and elastica had largely disappeared. The material stained blue with phosphotungstic acid hæmatoxylin. This type of change is to be differentiated from the bland hyaline thickening of arteriolosclerosis seen in the benign types of hypertension. The larger arterioles and small arteries were affected by a fine proliferative fibrosis of the intima, and the larger arteries presented a coarser type of fibrous intimal thickening with some degree of elastic reduplication.

In the non-scarred areas arteriolar necroses were just as plentiful, especially in relation to the pelvis (fig. 6). By contrast, cellular intimal thickening of the smaller arteries was inconspicuous in the areas of the kidney not involved in the inflammation. The main renal vessels were small but otherwise healthy.

Adrenal.—The vessels in the fat surrounding the adrenal gland showed medial hypertrophy but no other striking change. In the arterioles deep to the capsule there were fibrinoid necroses like those already described (fig. 7).

THE SECOND CASE

A girl, aged 11 years, was admitted to St. Mary's Hospital on April 2, 1946, under Dr. Lightwood.

History

For a year she had had attacks of headache, nausea, and vomiting: they lasted about twenty-four hours and occurred at first at three-month intervals and lately at weekly intervals. She had had frequency of micturition and thirst for the same period. She had got thinner in the last two months. She had had the usual childish illnesses, and her legs had been treated surgically for rickets. A year previously her perineum had been lacerated by falling on a spike. Her father, mother, and two sisters were alive and well; an aunt had high blood-pressure.

Examination

She was a pale and thin child, with arterial pressure 240/170 mm. Hg. Her heart showed no definite enlargement clinically. Her urine contained albumin, pus cells, and granular casts. There were no abnormal signs in her central nervous system.

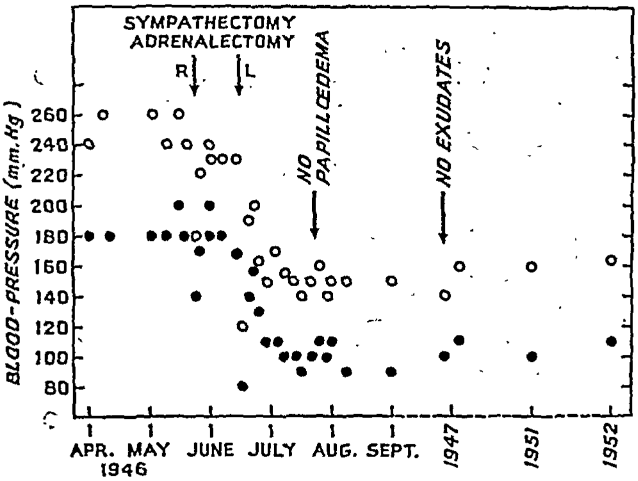

Fig. 8—Case 2: arterial pressure.

Her fundi showed bilateral papillœdema, with large ill-defined exudates, hæmorrhages, and star figures at both maculæ. Her blood-urea was 39 mg., falling later to 29 mg., per 100 ml.; urea concentration to 2·3%. Cultures of the urine were sometimes sterile, and sometimes grew *Bacterium coli*, *Staphylococcus albus*, or *Streptococcus fæcalis* (probably contaminants). Intravenous pyelography showed both kidneys functioning. Catheterisation of the ureters after administration of urea 15 g. yielded urine which on the left side contained albumin and up to 2·2% urea, and on the right albumin and 0·5% urea.

A diagnosis of bilateral pyelonephritis with malignant hypertension was made and 'Sulphamezathine' 1 g. was given six-hourly. The urine continued to show an excess of white cells. The arterial pressure continued to run between 240 and 260 mm. Hg systolic and 170 and 180 diastolic.

Operation (May 20, 1946)

The adrenal, the splanchnic nerves, and the upper lumbar sympathetic ganglia were excised on the right side. The right kidney was seen to be scarred. The operation was followed by no significant change in her blood-pressure or in her fundi. On June 13, 1946, three-quarters of the left adrenal, the left splanchnics, and the upper left lumbar ganglia were removed. The left kidney appeared normal.

Progress

After the second operation the blood-pressure fell and became steady at 130–145 mm. Hg systolic and 90–110 diastolic. When she was discharged on Aug. 3, the papillœdema had disappeared and the exudates were smaller and more sharply defined. Eucortone and deoxycortone were given after the second operation as for an addisonian crisis: no significant abnormality in blood-urea or serum-sodium was found, nor was pigmentation apparent; but the Kepler test on Aug. 1, 1946, was positive.

On March 3, 1947, papillœdema and exudates had quite disappeared, apart from a small circumscribed exudate on the left. Blood-pressure 140/100.

On March 13, 1951, the patient's breasts were well developed for her age, and she had grown as tall as her mother. Her fundi showed no papillœdema or exudates, and her blood-pressure was 164/104. Blood-urea 46 mg. per 100 ml. Urea concentration to 2·6%. Urine: trace of albumin, numerous red cells and pus cells, and a few hyaline and granular casts.

On March 27, 1952, she was well and living a fully active life. She had continued to grow and was taller than her mother. Blood-pressure 165/110. Fundi: no papillœdema, exudates or hæmorrhages. Blood-urea 41 mg. Urine: trace of albumin; red cells, white cells, and casts in excess. Fig. 8 shows the arterial pressure in this patient.

Operation Specimens

Right adrenal.—The right adrenal gland had a prominent medulla. The periadrenal arteries presented some degree of medial hypertrophy. The arterioles in the parenchyma, especially those underneath the capsule, showed the typical necrotising lesions described in case 1 (fig. 9).

Right kidney.—A small fragment of the right renal cortex was examined. One area was somewhat fibrotic, contained a hyalinised glomerulus, and was infiltrated with lymphocytes. The rest of the section was relatively normal with some arteriolar hyalinisation. No necroses were present, but the number of vessels examined, even when the entire block was sectioned serially, was of necessity small.

Left adrenal.—This had a well-developed cortex and medulla. A few subcapsular arterioles showed fibrinoid necrosis. Apart from medial hypertrophy of periadrenal arteries there were no other vascular changes.

Left kidney.—A small portion of the left renal cortex was examined. One area was fibrotic, contained a few atrophic tubules with colloid casts, and was infiltrated with lymphocytes. One arteriole in a normal part of the specimen showed fibrinoid change (fig. 10), whereas others were hyalinised.

THE THIRD CASE

A girl, aged 13, was admitted to Great Ormond Street Hospital under Dr. Donald Paterson in June, 1946.

History

She had had headache and listlessness on and off for four years and vomiting for a month. There was no history of œdema or of frequency of micturition, but a year previously she had passed blood in her urine. At the age of 2½ years she had been taken to Tite Street Hospital with attacks of listlessness. Her father, aged 38 (blood-pressure 124/82 mm. Hg), and her mother (blood-pressure 136/90) were both well, as were her younger sister and brother.

Examination

She was thin but maturely developed for her age; her blood-pressure was 256/180 mm. Hg; her fundi showed bilateral papillœdema, large soft exudates, and great narrowing of arteries. She had no pyrexia. A catheter specimen of urine showed 0·1% albumin and a moderate amount of red cells; culture grew *Bact. coli*. Urea clearance was 48 and 56% of normal; the blood-urea was 82 mg. per 100 ml. Excretion pyelography showed moderate excretion from both kidneys and some dilatation of the pelves. The left kidney was the smaller, excreted less well, and had a double ureter. The blood-urea fell to 34 mg., but the blood-pressure remained at about the same level. She had several attacks of very intense headache and disorientation.

Operation

On July 3, 1946, Mr. Twistington Higgins removed the left kidney. It was small, adherent, and fibrotic.

THE SECOND CASE

A girl, aged 11 years, was admitted to St. Mary's Hospital on April 2, 1946, under Dr. Lightwood.

History

For a year she had had attacks of headache, nausea, and vomiting: they lasted about twenty-four hours and occurred at first at three-month intervals and lately at weekly intervals. She had had frequency of micturition and thirst for the same period. She had got thinner in the last two months. She had had the usual childish illnesses, and her legs had been treated surgically for rickets. A year previously her perineum had been lacerated by falling on a spike. Her father, mother, and two sisters were alive and well; an aunt had high blood-pressure.

Examination

She was a pale and thin child, with arterial pressure 240/170 mm. Hg. Her heart showed no definite enlargement clinically. Her urine contained albumin, pus cells, and granular casts. There were no abnormal signs in her central nervous system.

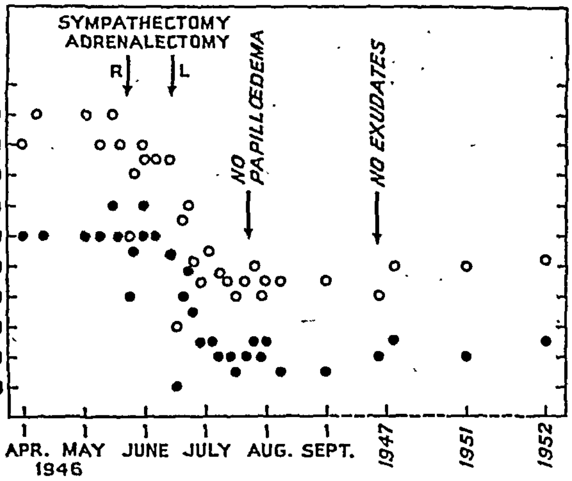

Fig. 8—Case 2: arterial pressure.

Her fundi showed bilateral papillœdema, with large ill-defined exudates, hæmorrhages, and star figures at both maculæ. Her blood-urea was 39 mg., falling later to 29 mg., per 100 ml.; urea concentration to 2·3%. Cultures of the urine were sometimes sterile, and sometimes grew *Bacterium coli*, *Staphylococcus albus*, or *Streptococcus fæcalis* (probably contaminants). Intravenous pyelography showed both kidneys functioning. Catheterisation of the ureters after administration of urea 15 g. yielded urine which on the left side contained albumin and up to 2·2% urea, and on the right albumin and 0·5% urea.

A diagnosis of bilateral pyelonephritis with malignant hypertension was made and 'Sulphamezathine' 1 g. was given six-hourly. The urine continued to show an excess of white cells. The arterial pressure continued to run between 240 and 260 mm. Hg systolic and 170 and 180 diastolic.

Operation (May 20, 1946)

The adrenal, the splanchnic nerves, and the upper lumbar sympathetic ganglia were excised on the right side. The right kidney was seen to be scarred. The operation was followed by no significant change in her blood-pressure or in her fundi. On June 13, 1946, three-quarters of the left adrenal, the left splanchnics, and the upper left lumbar ganglia were removed. The left kidney appeared normal.

Progress

After the second operation the blood-pressure fell and became steady at 130–145 mm. Hg systolic and 90–110 diastolic. When she was discharged on Aug. 3, the papillœdema had disappeared and the exudates were smaller and more sharply defined. Eucortone and deoxycortone were given after the second operation as for an addisonian crisis: no significant abnormality in blood-urea or serum-sodium was found, nor was pigmentation apparent; but the Kepler test on Aug. 1, 1946, was positive.

On March 3, 1947, papillœdema and exudates had quite disappeared, apart from a small circumscribed exudate on the left. Blood-pressure 140/100.

On March 13, 1951, the patient's breasts were well developed for her age, and she had grown as tall as her mother. Her fundi showed no papillœdema or exudates, and her blood-pressure was 164/104. Blood-urea 46 mg. per 100 ml. Urea concentration to 2·6%. Urine: trace of albumin, numerous *red cells and pus cells, and a few hyaline and granular casts.*

On March 27, 1952, she was well and living a fully active life. She had continued to grow and was taller than her mother. Blood-pressure 165/110. Fundi: *no papillœdema, exudates or hæmorrhages.* Blood-urea 41 mg. Urine: *trace of albumin*; red cells, white cells, and casts in excess. Fig. 8 shows the arterial pressure in this patient.

Operation Specimens

Right adrenal.—The right adrenal gland had a prominent medulla. The periadrenal arteries presented some degree of medial hypertrophy. The arterioles in the parenchyma, especially those underneath the capsule, showed the typical necrotising lesions described in case 1 (fig. 9).

Right kidney.—A small fragment of the right renal cortex was examined. One area was somewhat fibrotic, contained a hyalinised glomerulus, and was infiltrated with lymphocytes. The rest of the section was relatively normal with some arteriolar hyalinisation. No necroses were present, but the number of vessels examined, even when the entire block was sectioned serially, was of necessity small.

Left adrenal.—This had a well-developed cortex and medulla. A few subcapsular arterioles showed fibrinoid necrosis. Apart from medial hypertrophy of periadrenal arteries there were no other vascular changes.

Left kidney.—A small portion of the left renal cortex was examined. One area was fibrotic, contained a few atrophic tubules with colloid casts, and was infiltrated with lymphocytes. One arteriole in a normal part of the specimen showed fibrinoid change (fig. 10), whereas others were hyalinised.

THE THIRD CASE

A girl, aged 13, was admitted to Great Ormond Street Hospital under Dr. Donald Paterson in June, 1946.

History

She had had headache and listlessness on and off for four years and vomiting for a month. There was no history of œdema or of frequency of micturition, but a year previously she had passed blood in her urine. At the age of 2½ years she had been taken to Tite Street Hospital with attacks of listlessness. Her father, aged 38 (blood-pressure 124/82 mm. Hg), and her mother (blood-pressure 136/90) were both well, as were her younger sister and brother.

Examination

She was thin but maturely developed for her age; her blood-pressure was 255/180 mm. Hg; her fundi showed bilateral papillœdema, large soft exudates, and great narrowing of arteries. She had no pyrexia. A catheter specimen of urine showed 0·1% albumin and a moderate amount of red cells; culture grew *Bact. coli.* Urea clearance was 48 and 56% of normal; the blood-urea was 82 mg. per 100 ml. Excretion pyelography showed moderate excretion from both kidneys and some dilatation of the pelves. The left kidney was the smaller, excreted less well, and had a double ureter. The blood-urea fell to 34 mg., but the blood-pressure remained at about the same level. She had several attacks of very intense headache and disorientation.

Operation

On July 3, 1946, Mr. Twistington Higgins removed the left kidney. It was small, adherent, and fibrotic.

Fig. 6—Case 1: necroses in vessels situated in renal pelvis. (H. and E.) (× 260.)

Fig. 7—Case 1: arteriolar necrosis in adrenal. (H. and E.) (× 375.)

Fig. 9—Case 2: arteriolar necrosis in right adrenal. (H. and E.) (× 375.)

Progress

After operation the arterial pressure fell to 160/95, but by the following day it had risen to 210/170. Subsequently there was little change in blood-pressure or fundi. On Sept. 11, 1946, the blood-urea was 50 mg., and the urea clearance 87·6 and 101% of normal average. On Jan. 23, 1947, the blood-pressure was 220/150, and the albuminuric retinitis had not improved.

On Jan. 28, 1947, the patient was admitted to St. Mary's Hospital under Dr. Lightwood. The arterial pressure was 230/170: no pulsus alternans or gallop. The fundi showed gross papillœdema and peripapillary œdema. The arteries were very narrow and showed gross variation of calibre: the veins were full. Exudates were mainly sharply defined. The blood-urea was 32 mg. Urea concentration to 2·7%.

Further Operations

On Feb. 13, 1947, three-quarters of the right adrenal and a biopsy specimen of the right kidney were removed. The arterial pressure after an initial fall remained unaltered. On April 24, 1947, when the blood-pressure was 240/170, the whole of the left adrenal was removed. The splanchnics were left untouched on both sides.

Treatment and Progress

Preoperative and postoperative treatment with deoxycortone and adrenal cortical extract was given from April 21 to May 1, 1947. The arterial pressure was 206/160 on the evening of April 24, and fell to 170/104 on April 26. From then to discharge on May 23 it remained between 150/110 and 210/170. The serum-sodium, serum-potassium, and blood-urea levels remained normal. On Sept. 25, 1947, it was noted that conspicuous addisonian pigmentation had developed in the creases of the palms, on the backs of both hands, in the flexures of the knees, in the linea alba, in the areolæ of the breasts, and in the scar of the left lumbar incision. Blood-pressure 185/145. Both optic discs were clear, with a sharp nasal edge and a few small sharply defined punctate exudates.

When the patient was seen at intervals, her blood-pressure remained between 250/150 and 220/115. On Jan. 4, 1951, it was 230/154. Fundi: discs clear and pale; arteries thin, conspicuously irregular and rather pale, a few small branches seen as white streaks: a small exudate at 2 o'clock rather far out; several scars of old exudates; and several new vessels on the left disc. The urine contained albumin.

On Aug. 22, 1951, the patient felt well; her height was 5 ft. 5 in. and weight 8 st. 4 lb.; her blood-pressure was 235/155; and her urine contained albumin and a slight excess of white cells. Her pigmentation was less but still pronounced on the dorsum of the fingers. Her fundi were as before.

She was readmitted on Nov. 21, 1951, for further treatment of her hypertension. She was subjectively well and doing a full day's work. Her arterial pressure was 220/150 on admission, but settled to between 180–200 systolic and 110–120 diastolic when she had rested for a week. Her urine contained albumin and a slight excess of red cells, leucocytes, and granular casts; it was sterile on culture. Her blood-urea level was 22 mg. per 100 ml. Urea concentration to 2·4%. An excretion urogram of the right kidney was normal. She was treated with chloramphenicol and hexamethonium. Fig. 11 summarises the changes in blood-pressure.

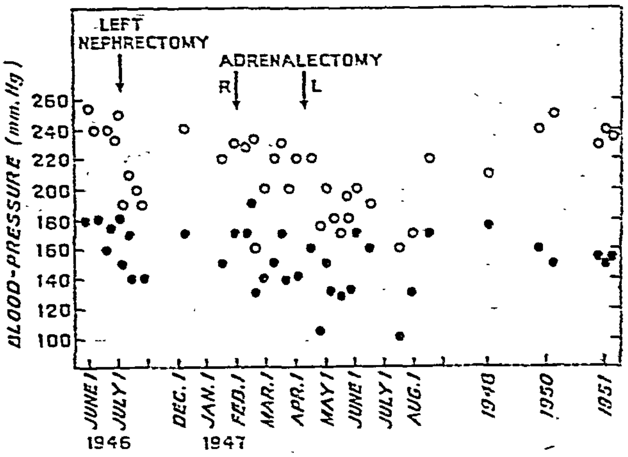

Fig. 11—Case 3: arterial pressure.

Operation Specimens

Left kidney.—This measured 6·0 × 2·5 × 1·5 cm. and had a coarsely nodular surface. Two ureters were present, one draining the upper calyx, and the other the remainder of the kidney. The pelvic wall was thickened and fibrous, and the calyces were dilated. In the scarred areas the parenchyma was reduced to 0·2 cm. Microscopy showed chronic pyelonephritis. The areas of old inflammation showed increased fibrosis, considerable numbers of lymphocytes, and no glomeruli. In places the glomeruli had not disappeared completely but were represented by hyalinised spheres. The tubules were atrophic and contained colloid-like casts. As in case 1, there were relatively normal areas of parenchyma between the scarred zones. The pelvis was thickened by fibrous tissue and infiltrated with lymphocytes and plasma cells.

Vascular changes again differed in the scarred and non-scarred areas. Fibrinoid necroses were present in both in exactly the same way as in case 1, and intimal proliferation occurred in the small arteries in the scars, but only to a minor degree in the non-scarred parts. The general pattern was very similar to that of case 1, except that necroses were more numerous.

Right adrenal.—Very many typical necroses were present among the arterioles and small arteries in the substance of the gland (figs. 12 and 13), and were more numerous and much more conspicuous in this than in any other adrenal here described. Similar widespread necroses were present in the periadrenal vessels (fig. 14), in one instance being associated with a well-marked cellular reaction, such as is seen in periarteritis nodosa.

Left adrenal.—Vascular changes were much less conspicuous. Necroses were, however, present in the parenchymal arterioles, especially in those underneath the capsule.

DISCUSSION

In each of these three patients the lesion underlying the hypertension was pyelonephritis. In case 1 the persistent reduction of arterial pressure following operation may be attributed to removal of the diseased kidney, the other being apparently normal; other such cases are being reported elsewhere (Pickering and Heptinstall 1952). It seems unlikely that the excision of sympathetic nerves and adrenal had anything to do with the fall of blood-pressure, since in other cases in which these structures alone have been excised unilaterally, hypertension has not been materially or persistently altered. In case 3 removal of the more affected kidney produced a transient fall of arterial pressure that was not maintained, but the disease was bilateral. Since albuminuric retinitis persisted and the arterial pressure remained very high, the whole of one adrenal and three-

Fig. 2—Necropsy specimen of lung injected with radio-opaque solution into azygos vein. Injection of azygos vein has filled pulmonary veins.

Fig. 3—Dissection of mediastinum showing dilated tortuous pleurohilar veins at mediastino-pulmonary junction in a case of severe mitral stenosis.

quarters of the other were removed, substitution therapy being given for three days before and seven after the operation; as this was withdrawn, the arterial pressure fell profoundly, later rising, but never quite to the preoperative level. In case 2, also of bilateral disease, neither kidney was excised, but an infradiaphragmic sympathectomy with removal of one adrenal and three-quarters of the other produced a profound and persistent fall of arterial pressure.

Though the intervention that caused the arterial pressure to fall thus differed, the effects of the fall in pressure were similar in the three cases. Albuminuric retinitis cleared, and the pattern of its clearing was similar in all. Neuroretinal œdema resolved first. Papillœdema went next, and the exudates became smaller and sharply defined, the picture now resembling that of arteriosclerotic retinitis except for bilateral involvement and the macular star, which in case 1 resolved last. C.S.F. pressures were not measured, but the resolution of the retinitis supports the idea previously presented (Pickering 1934) that neuroretinal œdema is a separate, and the distinctive, component of albuminuric retinitis.

Acute arteriolar necroses were found in kidney and adrenal of all three patients at operation. Since these were the only tissues examined, the necroses may be presumed to have had their usual distribution in the organs of the body. No further biopsy specimens were obtained, but the absence of subjective symptoms, a normal blood-urea, and an ability to concentrate urea in the urine to over 2% five or six years after operation provide strong evidence that these acute arteriolar necroses had ceased to occur and had presumably healed. Acute arteriolar necroses in the pyelonephritic areas of the kidney might have been due to the inflammation; but their occurrence in those areas of kidney that were not inflamed, especially in the adrenal, excludes this cause. None of the patients were uræmic, and there is nothing in the case records to suggest that a renal substance was the cause of the necroses. In fact, the presence of these acute necroses at operation and their subsequent behaviour are easily explained only by the hypothesis that they are caused by a rise in intravascular pressure above a certain point. In case 3, with a diastolic pressure of 160–180 mm. Hg before operation and a diastolic pressure which six months after adrenalectomy and subsequently lay between 130 and 160 mm. Hg, this threshold level must have been high. She alone after operation presented gross evidence of organic disease in the retinal arteries, presumably representing healed acute lesions; how far such healed lesions, which presumably healed during the period of low pressure following adrenalectomy, protected the vessels distally from raised arterial pressure is problematical.

Volhard (1931) originally suggested, and Wilson and Byrom (1941) produced experimental evidence for, the idea of a vicious circle in Bright's disease. According to this hypothesis ischæmia produced by acute arteriolar necroses in the kidney releases a renal substance which maintains and enhances hypertension. There is no direct evidence for this hypothesis in man, and the striking and maintained fall in arterial pressure following nephrectomy in case 1, with severe necroses in both kidney and adrenal, is against its being an important factor in the maintenance of hypertension. Even if a vicious circle exists it can clearly be broken.

The therapeutic implications of the hypothesis supported here are plain. Malignant hypertension is characterised by acute arteriolar necroses, and these necroses usually kill by producing renal failure. Sometimes they develop quickly, and the transition from intact renal function to death in uræmia may be a matter of a few weeks only. Once malignant hypertension is diagnosed—and it is diagnosed by the fundus oculi—treatment is urgent and is directed to one single end, the reduction of arterial pressure. Sometimes this may be achieved by removing the cause, a unilaterally diseased kidney or an adrenal medullary or adrenal cortical tumour. Sometimes it can be achieved only by a less direct approach—sympathectomy, salt-free diet, pyrogens, or hexamethonium compounds. Of these, sympathectomy, because it involves no prolonged restrictions and may have a persistent effect, will have a large place until something better is available. Hexamethonium compounds have the great virtue that they can be effective at once and in nearly all cases, except those too advanced for any therapy. Their chief disadvantage is the extent to which they interfere with the patient's way of life. Subtotal adrenalectomy was used in two of the cases reported here, combined with sympathectomy in one, and it was used in a similar case to be reported elsewhere (Pickering and Heptinstall 1952). It was, up to a point, effective. We have also used it in three adults in the malignant phase of essential hypertension, but with less success. Whether the success in the pyelonephritics was due to their youth, to the mechanism of hypertension, or to their being in a less advanced stage of the disease, is a question we leave without further comment.

SUMMARY

Three cases are reported in which the malignant was converted to the benign form of hypertension by operations persistently reducing arterial pressure. All three patients had pyelonephritis. Arterial pressure was reduced by nephrectomy in one, by subtotal adrenalectomy in another, and by sympathectomy and subtotal adrenalectomy in a third.

At operation all three patients had albuminuric retinitis, and acute arteriolar necroses in kidney and adrenal. All are alive and symptomatically well five or six years after operation, with less severe hypertension, a normal blood-urea level, and normal urea concentration.

These observations demonstrate conclusively that malignant hypertension is reversible, and support the hypothesis that the benign and malignant forms are simple consequences of the severity of the hypertension.

We wish to thank our colleagues for referring these cases to us and Dr. Martin Bodian for the kidney of case 3. Cases 1 and 3 are summarised as cases 11 and 3 in the article by Pickering and Heptinstall (1952).

THE RÔLE OF THE BRONCHIAL VEINS IN MITRAL STENOSIS

J. C. Gilroy

Anatomical studies of the bronchial vascular system have directed our attention to the possible rôle of the bronchial veins as a decompressive mechanism in pulmonary venous hypertension. In previous papers we have described two systems of bronchial vessels:

(1) The true bronchial vessels which accompany the bronchi as far as the respiratory bronchiole.

(2) The "pleurohilar" vessels which supply and drain the hilar structures and the subpleural plane. (Marchand et al. 1950).

The arrangement of the pleurohilar system seemed so well adapted to afford a decompressive mechanism in pulmonary venous hypertension that we began to look for evidence of a functional alteration in these veins in cases of mitral stenosis.

It is generally accepted that mitral stenosis causes a rise in pressure within the pulmonary veins largely due to the mechanical obstruction to the passage of blood from the pulmonary into the systemic circulation. The rise in pulmonary venous pressure may in itself act as a compensatory mechanism by creating a greater speed of blood-flow through the narrow mitral orifice. When the left auricle is relatively healthy, this effect may be augmented by muscular hypertrophy of the auricle. Increase in the pulmonary venous pressure raises the pulmonary arterial pressure. The precise cause of this rise is uncertain, but the effect is to maintain an effective pressure gradient between pulmonary artery and vein. As a consequence of the pulmonary hypertension the right ventricle hypertrophies, and as the pulmonary engorgement progresses the pulmonary artery dilates. Engorgement of the pulmonary circulation is considered to be intimately concerned with the dyspnœa of mitral stenosis even before congestive cardiac failure supervenes (Wood 1950), and is probably closely connected with the occurrence of pulmonary œdema. It has long been recognised that, where a defect in the auricular septum is present, pulmonary œdema may be long delayed (Bedford et al. 1941). Bland and Sweet (1949) evolved an operation to relieve the symptoms of severe mitral stenosis by making an anastomosis between a branch of the pulmonary vein and the azygos vein. The rationale of this operation was based upon the work of Ferguson et al. (1944), who postulated a shunt of blood from the engorged pulmonary veins of mitral stenosis into the bronchial veins which, they maintained, drained into the azygos and hemiazygos veins. The conclusions of these workers were based largely on the anatomical descriptions of Miller (1947) and they themselves undertook no detailed anatomical studies to confirm their views. It is therefore well recognised that pulmonary engorgement may, to some extent, be compensated for by a shunting of blood from the pulmonary to the systemic veins. We have been especially concerned with the exact anatomical route whereby this effect is accomplished. Certain other features, such as the so-called stiff lung or *Lungenstarre* described by German workers, and the hæmoptysis of mitral stenosis, can also, we believe, be explained upon an anatomical basis.

MATERIAL AND METHODS OF EXAMINATION

The true bronchial veins have been studied in five necropsy specimens of normal lungs, and the pleurohilar veins in fourteen specimens: the results have been described in detail elsewhere (Marchand et al. 1950) but are summarised here.

Six patients with mitral stenosis were investigated at necropsy. In these cases the pleurohilar veins were dissected. Thirty patients were observed during valvulotomy for mitral stenosis.

NORMAL ANATOMY

Two distinct systems of bronchial veins have been distinguished: (1) the true bronchial veins, which drain the intrapulmonary bronchi and the supporting interstitial framework of the lung; and (2) the pleurohilar veins, which drain the hilar structures and the subpleural planes of the lung. The true bronchial veins drain into

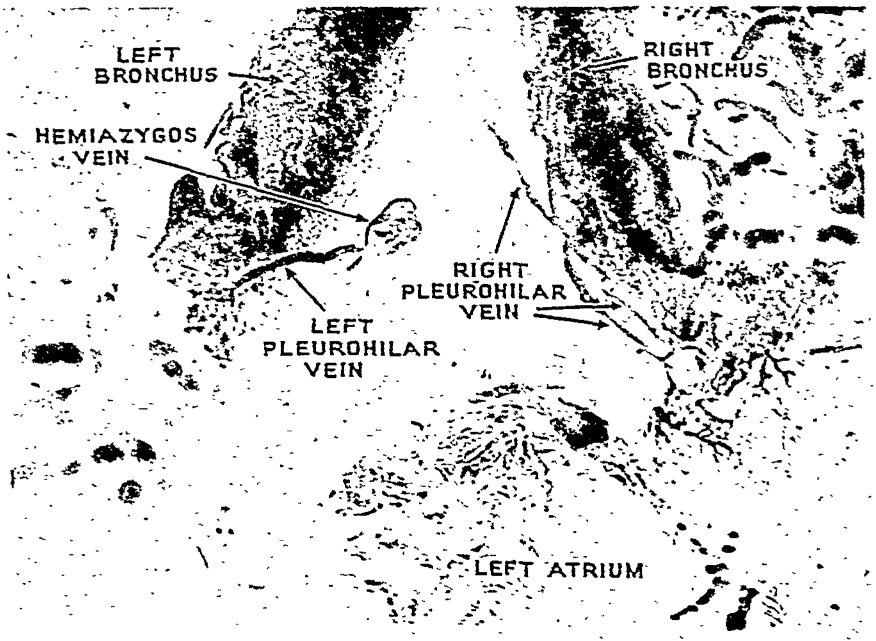

Fig. 1—Vinylite cast of normal lung viewed from behind. Bronchus is filled with Wood's metal, pulmonary arteries with blue vinylite, and pulmonary veins with red vinylite. Pleurohilar veins have been filled through pulmonary veins, and on left side entry of pleurohilar vein into hemiazygos vein has been demonstrated. Entry of right pleurohilar vein into azygos vein is not shown.

quarters of the other were removed, substitution therapy being given for three days before and seven after the operation; as this was withdrawn, the arterial pressure fell profoundly, later rising, but never quite to the preoperative level. In case 2, also of bilateral disease, neither kidney was excised, but an infradiaphragmic sympathectomy with removal of one adrenal and three-quarters of the other produced a profound and persistent fall of arterial pressure.

Though the intervention that caused the arterial pressure to fall thus differed, the effects of the fall in pressure were similar in the three cases. Albuminuric retinitis cleared, and the pattern of its clearing was similar in all. Neuroretinal œdema resolved first. Papillœdema went next, and the exudates became smaller and sharply defined, the picture now resembling that of arteriosclerotic retinitis except for bilateral involvement and the macular star, which in case 1 resolved last. C.S.F. pressures were not measured, but the resolution of the retinitis supports the idea previously presented (Pickering 1934) that neuroretinal œdema is a separate, and the distinctive, component of albuminuric retinitis.

Acute arteriolar necroses were found in kidney and adrenal of all three patients at operation. Since these were the only tissues examined, the necroses may be presumed to have had their usual distribution in the organs of the body. No further biopsy specimens were obtained, but the absence of subjective symptoms, a normal blood-urea, and an ability to concentrate urea in the urine to over 2% five or six years after operation provide strong evidence that these acute arteriolar necroses had ceased to occur and had presumably healed. Acute arteriolar necroses in the pyelonephritic areas of the kidney might have been due to the inflammation; but their occurrence in those areas of kidney that were not inflamed, especially in the adrenal, excludes this cause. None of the patients were uræmic, and there is nothing in the case records to suggest that a renal substance was the cause of the necroses. In fact, the presence of these acute necroses at operation and their subsequent behaviour are easily explained only by the hypothesis that they are caused by a rise in intravascular pressure above a certain point. In case 3, with a diastolic pressure of 160–180 mm. Hg before operation and a diastolic pressure which six months after adrenalectomy and subsequently lay between 130 and 160 mm. Hg, this threshold level must have been high. She alone after operation presented gross evidence of organic disease in the retinal arteries, presumably representing healed acute lesions; how far such healed lesions, which presumably healed during the period of low pressure following adrenalectomy, protected the vessels distally from raised arterial pressure is problematical.

Volhard (1931) originally suggested, and Wilson and Byrom (1941) produced experimental evidence for, the idea of a vicious circle in Bright's disease. According to this hypothesis ischæmia produced by acute arteriolar necroses in the kidney releases a renal substance which maintains and enhances hypertension. There is no direct evidence for this hypothesis in man, and the striking and maintained fall in arterial pressure following nephrectomy in case 1, with severe necroses in both kidney and adrenal, is against its being an important factor in the maintenance of hypertension. Even if a vicious circle exists it can clearly be broken.

The therapeutic implications of the hypothesis supported here are plain. Malignant hypertension is characterised by acute arteriolar necroses, and these necroses usually kill by producing renal failure. Sometimes they develop quickly, and the transition from intact renal function to death in uræmia may be a matter of a few weeks only. Once malignant hypertension is diagnosed—and it is diagnosed by the fundus oculi—treatment is urgent and is directed to one single end, the reduction of arterial pressure. Sometimes this may be achieved by removing the cause, a unilaterally diseased kidney or an adrenal medullary or adrenal cortical tumour. Sometimes it can be achieved only by a less direct approach—sympathectomy, salt-free diet, pyrogens, or hexamethonium compounds. Of these, sympathectomy, because it involves no prolonged restrictions and may have a persistent effect, will have a large place until something better is available. Hexamethonium compounds have the great virtue that they can be effective at once and in nearly all cases, except those too advanced for any therapy. Their chief disadvantage is the extent to which they interfere with the patient's way of life. Subtotal adrenalectomy was used in two of the cases reported here, combined with sympathectomy in one, and it was used in a similar case to be reported elsewhere (Pickering and Heptinstall 1952). It was, up to a point, effective. We have also used it in three adults in the malignant phase of essential hypertension, but with less success. Whether the success in the pyelonephritics was due to their youth, to the mechanism of hypertension, or to their being in a less advanced stage of the disease, is a question we leave without further comment.

SUMMARY

Three cases are reported in which the malignant was converted to the benign form of hypertension by operations persistently reducing arterial pressure. All three patients had pyelonephritis. Arterial pressure was reduced by nephrectomy in one, by subtotal adrenalectomy in another, and by sympathectomy and subtotal adrenalectomy in a third.

At operation all three patients had albuminuric retinitis, and acute arteriolar necroses in kidney and adrenal. All are alive and symptomatically well five or six years after operation, with less severe hypertension, a normal blood-urea level, and normal urea concentration.

These observations demonstrate conclusively that malignant hypertension is reversible, and support the hypothesis that the benign and malignant forms are simple consequences of the severity of the hypertension.

We wish to thank our colleagues for referring these cases to us and Dr. Martin Bodian for the kidney of case 3. Cases 1 and 3 are summarised as cases 11 and 3 in the article by Pickering and Heptinstall (1952).

of the right heart is not materially increased, its work is augmented by the increased pulmonary arterial pressure. The circuit described, whereby blood from the right ventricle is returned to the right auricle without traversing the left side of the heart, may materially increase the volume of blood presented to the right ventricle and so impose an additional load on the right side of the heart. If such a circus movement is possible, it must challenge the validity of the concept that the output of the left ventricle is of necessity identical with the output of the right; for in mitral stenosis, and possibly in other causes of pulmonary venous hypertension, the right ventricle may put out more blood per unit of time than the left ventricle.

The tissues drained by the pleurohilar and true bronchial veins are enclosed by the peribronchial prolongations of the perivisceral fascia (Marchand 1951). Within the lung this area is drained by the true bronchial veins and is entirely separated from the alveoli by the peribronchial fascia. The true bronchial veins, by virtue of their free communication with the pulmonary veins, are subjected to any increase in pressure which may develop in the pulmonary venous system. The features of the stiff lung of mitral stenosis are those of an interstitial œdema. *Lungenstarre* or "stiff lung" was described by Schoen (1930) and Sylla (1935); but these workers held it to be due to congestion of the pulmonary veins and arteries, a pathology originally postulated by Vieussens (1715). Sylla (1935) described a macroscopic increase in the supporting tissues of the lung, and White (1947) states that in mitral stenosis there is a "tendency to bleeding or diffusion of serum (œdema) into the interstitial tissues of the lung." "This," he states, "develops into an extreme interstitial fibrosis which may in time resemble 'malignant pulmonary sclerosis' due to other causes." He also attributes this to engorgement of the pulmonary circulation, but it is difficult to envisage an interstitial œdema arising from a "leak in the pulmonary vein." An effusion originating from the capillaries of the true bronchial veins, however, would remain entirely interstitial. Ferguson et al. (1944) have shown that the intrabronchial tributaries of the bronchial vein are dilated in mitral stenosis. This is to be expected when it is realised that the bronchial veins drain into the pulmonary vein and not into the systemic veins as described by Miller (1947). Thus it is logical to presume that in mitral stenosis there is a rise in bronchial venous pressure, which in time may cause a transudation of œdema fluid into the supporting interstitial framework of the lung, and the development of a rigid or stiff lung without any intra-alveolar pulmonary œdema.

Apart from these considerations, it is possible that the pleurohilar and true bronchial veins play an important part in other aspects of the disease picture of mitral stenosis. Fig. 5 represents diagrammatically the possible functions of these veins in modifying the sequence of events leading to the end-results of mitral stenosis.

SUMMARY

Six cases of mitral stenosis have been studied anatomically at necropsy, and in thirty patients the condition of the lungs was observed at operation.

Striking engorgement of the pleurohilar veins was noted in all the cases in which they were exposed by dissection.

The possible function of the pleurohilar veins as a decompressive mechanism in patients with pulmonary venous hypertension is discussed, and the probable effects of this mechanism on the symptoms of mitral stenosis are considered.

Our thanks are due to Mr. L. Fatti for allowing us access to his operations; to Dr. A. C. Watt and Mr. A. Hughes for the photographs; and to Dr. M. Findlay, of the radiological department, for the X-ray investigations.

Few serious toxic reactions have been reported during the use of isoniazid (isonicotinic acid hydrazide) in doses of 3 to 5 mg. per kg. body-weight per day. The Committee on Therapy of the American Trudeau Society (1952) summarise the preliminary clinical reports and quotes isolated instances of intractable asthma, persistent hypotension, and increased susceptibility to the effects of other drugs (but in this case the cause has not been clearly established). Less serious effects which have been reported are constipation, postural hypotension and dizziness, exaggerated reflexes, eosinophilia, difficulty in starting micturition, and the appearance of casts, albumin, and reducing substances in the urine. The first report of a symptom which suggested vitamin-B_2 deficiency during isoniazid therapy was by Pegum (1952), whose patient complained of "burning feet," a symptom which has been ascribed to deficiency of pantothenic acid.

In the following case severe symptoms and signs of pellagra developed within three weeks of starting treatment with isoniazid.

CASE-REPORT

A man, aged 22, had no family history of tuberculosis or mental disease, and had had no serious illness until two years ago. Occasional abdominal pains began in December, 1950, and the diagnosis of tuberculous peritonitis was confirmed by laparotomy and biopsy of the omentum in May, 1951. At first he responded to streptomycin and *p*-aminosalicylic acid (P.A.S.), but while in a sanatorium from July to December, 1951, his condition deteriorated. "The food did not agree with him," the abdominal pains returned, he lost his appetite, vomited often, and had diarrhœa, and his weight fell from 158 to 112 lb.

He returned home in December, 1951; his condition improved slightly and he stopped losing weight. He still had abdominal pain and loose stools (1 to 3 stools per day), but his appetite returned and he vomited only occasionally. In February, 1952, he had a further course of streptomycin at home but without benefit. During the four months before his admission to this hospital, his diet included plenty of eggs in milk and 1 lb. of a milk-protein preparation each week.

He was admitted on July 21, 1952. His weight was 112 lb., and he was emaciated. Abdominal examination was normal, except for several areas of tenderness. He was afebrile, his tongue was clean, and there were no abnormal signs in the respiratory or nervous systems. He had the introspection of the chronic tuberculous patient, but he was sensible and intelligent; his mood was rather depressed and resigned.

Hæmoglobin level was 9·8 g. per 100 ml and erythrocyte-sedimentation rate (Wintrobe) (corrected reading) 20 mm. in one hour. X-ray examination of the chest and abdomen and intravenous pyelograms were normal. The fæces and urine were repeatedly examined for tubercle bacilli, but none were found. However, treatment was started with isoniazid, 200 mg. twice daily (8 mg. per kg. body-weight per day), on July 28.

the pulmonary veins, whereas the pleurohilar veins empty into systemic veins, such as the azygos, hemiazygos, and intercostal veins (fig. 4).

The pleurohilar veins communicate freely with the pulmonary veins both at the hilum and in the subpleural plane (fig. 2).

Miller (1947) did not distinguish between these two systems of vessels. The veins which he describes as bronchial and which drain into systemic veins do not, in normal circumstances, drain more than the extrapulmonary bronchi, the hilar lymph-glands, and the other mediastinal structures at the hilum of the lung. These veins we have named the pleurohilar veins.

The true bronchial veins within the lung-substance course along a definite fascial plane which is an extension of the mediastinal perivisceral fascia (Marchand 1951). This fascia in the mediastinum encircles the trachea and œsophagus, and is prolonged into the lung as an investing layer of the bronchi and the pulmonary vessels. Situated within the plane between the bronchial wall and the peribronchial fascia lie the main trunks of the true bronchial veins, the true bronchial arteries, and the lymphatics of the lung. Venous tributaries from the intramural bronchial veins enter the venous trunks along the whole length of their course, particularly at the points of bronchial division. The peribronchial fascia is prolonged round the bronchi as far as the bronchioles and possibly may form the alveolar septum. The fascia therefore separates the respiratory portion of the lung from the interstitial framework, and the bronchial veins, which lie within the plane demarcated by this fascia, constitute the sole venous drainage of the supporting tissue of the lung.

FINDINGS IN MITRAL STENOSIS

At necropsy in all six cases of mitral stenosis congestion and dilatation of the pleurohilar veins in the mediastinum were observed. These normally insignificant veins were much distended and in two cases of tight mitral stenosis were tortuous and varicose (fig. 3). Injection of dye showed that they communicated freely with the pulmonary veins and drained directly into the azygos and hemiazygos veins.

The true bronchial veins lying within the peribronchial fascial planes have been found similarly dilated in patients who have died with mitral stenosis. The extrabronchial dilatation may be demonstrated by making a 'Vinylite' cast of the pulmonary venous tree (Marchand et al. 1950), and the intrabronchial dilatation of submucous and muscular tributaries of the bronchial veins can readily be demonstrated by injecting the pulmonary veins with a lead-gelatin mixture (Ferguson et al. 1944).

Recent developments in cardiac surgery have afforded the opportunity of more direct study of the pulmonary conditions in mitral stenosis. Dilatation of the subpleural veins over the costal surface of the lung has not been an obvious feature, but usually the veins close to the mediastinum have been prominent and thin walled. It has also been noted that the mediastinal veins at the hilum have appeared unduly congested. A feature often observed by surgeons performing mitral valvulotomy has been the difficulty experienced in collapsing the lungs after the chest has been opened. In the 30 cases observed, some degree of "stiffness of the lung" was encountered in 8. This slowness in collapsing is peculiar in that the lungs do not appear to be waterlogged, and pressure on them does not result in flooding of the trachea with expressed exudate. Once reduced in size by firm steady pressure, the lung can be reinflated without difficulty by the anæsthetist. The cause of the "stiffness" does not, therefore, seem to be within the alveoli or the lumina of the bronchi.

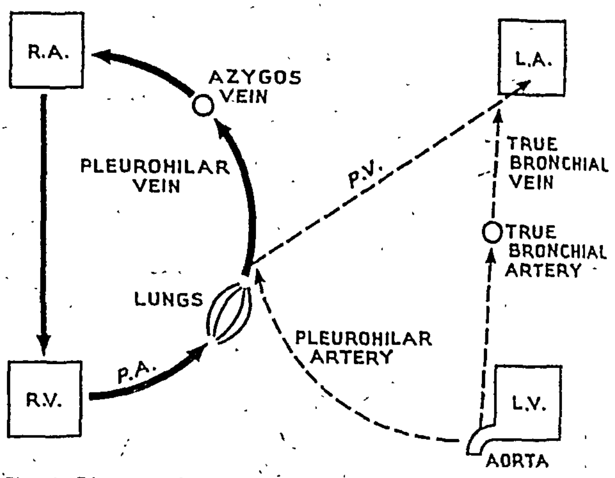

Fig. 4—Diagram of pulmonary and bronchial circulations. Circu movement described in mitral stenosis is shown in solid black.

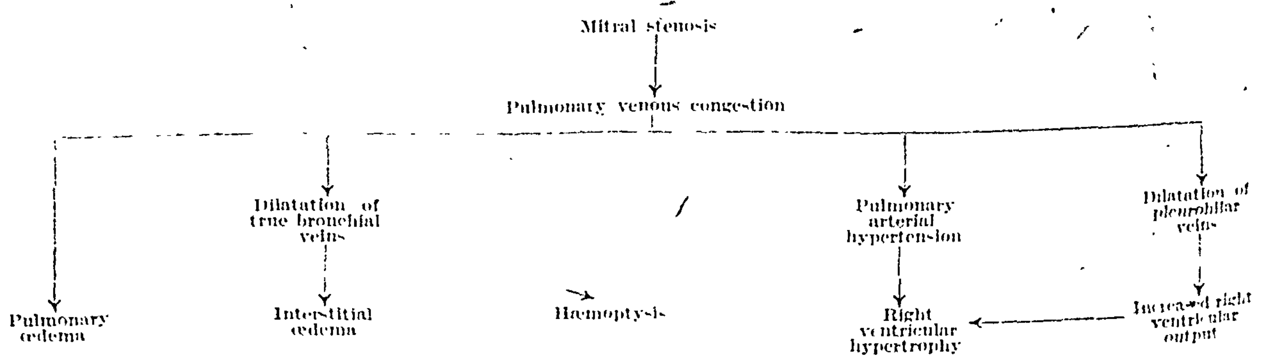
DISCUSSION

The necropsy observation that the pleurohilar veins are dilated in advanced cases of mitral stenosis supports the belief that there is a natural decompressive arrangement within the pulmonary circulation. Even in normal circumstances the pressure in the pulmonary vein is slightly higher than that of the superior vena cava, and in mitral stenosis this pressure must be increased. The pleurohilar veins constitute a mechanism whereby the rise in pressure in the pulmonary veins may be modified. The degree of dilatation of the pleurohilar veins which has been found indicates that considerable amounts of blood may take part in a circus movement through them from right ventricle to right auricle (fig. 4).

Swan (1949) has pointed out that the pathogenesis of right-sided heart-failure consequent on mitral stenosis has never been established by adequate experimental or clinical data. He states that, although the output



Mitral stenosis
Pulmonary venous congestion
Dilatation of true bronchial veins
Pulmonary arterial hypertension
Dilatation of pleurohilar veins
Pulmonary œdema
Interstitial œdema
Hæmoptysis
Right ventricular hypertrophy
Increased right ventricular output

Fig. 5—Sequence of events leading to end-results of mitral stenosis.

of the right heart is not materially increased; its work is augmented by the increased pulmonary arterial pressure. The circuit described, whereby blood from the right ventricle is returned to the right auricle without traversing the left side of the heart, may materially increase the volume of blood presented to the right ventricle and so impose an additional load on the right side of the heart. If such a circus movement is possible, it must challenge the validity of the concept that the output of the left ventricle is of necessity identical with the output of the right; for in mitral stenosis, and possibly in other causes of pulmonary venous hypertension, the right ventricle may put out more blood per unit of time than the left ventricle.

The tissues drained by the pleurohilar and true bronchial veins are enclosed by the peribronchial prolongations of the perivisceral fascia (Marchand 1951). Within the lung this area is drained by the true bronchial veins and is entirely separated from the alveoli by the peribronchial fascia. The true bronchial veins, by virtue of their free communication with the pulmonary veins, are subjected to any increase in pressure which may develop in the pulmonary venous system. The features of the stiff lung of mitral stenosis are those of an interstitial œdema. *Lungenstarre* or "stiff lung" was described by Schoen (1930) and Sylla (1935); but these workers held it to be due to congestion of the pulmonary veins and arteries, a pathology originally postulated by Vieussens (1715). Sylla (1935) described a macroscopic increase in the supporting tissues of the lung, and White (1947) states that in mitral stenosis there is a "tendency to bleeding or diffusion of serum (œdema) into the interstitial tissues of the lung." "This," he states, "develops into an extreme interstitial fibrosis which may in time resemble 'malignant pulmonary sclerosis' due to other causes." He also attributes this to engorgement of the pulmonary circulation, but it is difficult to envisage an interstitial œdema arising from a "leak in the pulmonary vein." An effusion originating from the capillaries of the true bronchial veins, however, would remain entirely interstitial. Ferguson et al. (1944) have shown that the intrabronchial tributaries of the bronchial vein are dilated in mitral stenosis. This is to be expected when it is realised that the bronchial veins drain into the pulmonary vein and not into the systemic veins as described by Miller (1947). Thus it is logical to presume that in mitral stenosis there is a rise in bronchial venous pressure, which in time may cause a transudation of œdema fluid into the supporting interstitial framework of the lung, and the development of a rigid or stiff lung without any intra-alveolar pulmonary œdema.

Apart from these considerations, it is possible that the pleurohilar and true bronchial veins play an important part in other aspects of the disease picture of mitral stenosis. Fig. 5 represents diagrammatically the possible functions of these veins in modifying the sequence of events leading to the end-results of mitral stenosis.

SUMMARY

Six cases of mitral stenosis have been studied anatomically at necropsy, and in thirty patients the condition of the lungs was observed at operation.

Striking engorgement of the pleurohilar veins was noted in all the cases in which they were exposed by dissection.

The possible function of the pleurohilar veins as a decompressive mechanism in patients with pulmonary venous hypertension is discussed, and the probable effects of this mechanism on the symptoms of mitral stenosis are considered.

He still had abdominal pain and loose stools (1 to 3 stools per day), but his appetite returned and he vomited only occasionally. In February, 1952, he had a further course of streptomycin at home but without benefit. During the four months before his admission to this hospital, his diet included plenty of eggs in milk and 1 lb. of a milk-protein preparation each week.

He was admitted on July 21, 1952. His weight was 112 lb., and he was emaciated. Abdominal examination was normal, except for several areas of tenderness. He was afebrile, his tongue was clean, and there were no abnormal signs in the respiratory or nervous systems. He had the introspection of the chronic tuberculous patient, but he was sensible and intelligent; his mood was rather depressed and resigned.

Hæmoglobin level was 9·8 g. per 100 ml. and erythrocyte-sedimentation rate (Wintrobe) (corrected reading) 20 mm. in one hour. X-ray examination of the chest and abdomen and intravenous pyelograms were normal. The fæces and urine were repeatedly examined for tubercle bacilli, but none were found. However, treatment was started with isoniazid, 200 mg. twice daily (8 mg. per kg. body-weight per day), on July 28.

There was little change in his condition at first, but after a week the stools increased from 3 to 6 per day and became very offensive. By Aug. 10 he had become very depressed and slightly irrational, and it was noticed that the dorsum of each hand was red and roughened. His mental condition deteriorated rapidly and by Aug. 15 he was refusing to eat. The diarrhœa had become more frequent, and on Aug. 17 he became incontinent of urine and fæces.

The next day isoniazid was stopped, and a psychiatrist who saw him reported that he was suffering from a schizophrenic reaction which presented many catatonic features. He had marked thought-blocking, incongruity between emotion and stimulus, ambivalence, sudden impulsive movements, and possibly hallucinations. On Aug. 20 he was worse, being quite irrational and possibly suicidal.

By now the redness on the dorsum of his hands was typical of pellagra, and it had spread symmetrically to above the wrists, where there was a sharp line of demarcation with the healthy skin. He also had cheilosis, redness of the nasolabial folds, and was incontinent of frequent watery stools.

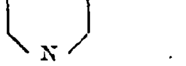
On Aug. 20 treatment was started with four-hourly doses of nicotinic acid, 40 mg. intramuscularly and 50 mg. by mouth, and vitamin-B complex intramuscularly twice daily. On Aug. 22 he was less disturbed mentally, he was able to take a high protein diet, and he was no longer incontinent, but still had much diarrhœa. By Aug. 24 his mental symptoms had all disappeared, the hand lesions were clearing, and the diarrhœa was less. By Sept. 1, the skin lesions had disappeared, and he was passing only 2 to 4 semiformed stools per day. His weight, which had remained at 112 lb. until Aug. 24, was now 120 lb. On Sept. 19 his weight was 131 lb. and he was only passing 1 or 2 semiformed stools per day, but the abdominal pains were still troubling him several times each day.

DISCUSSION

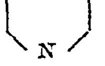
It is possible that on admission to hospital this patient was suffering from a deficiency of the B group of vitamins, though there were no symptoms or signs of this. His intake of vitamins was probably adequate, for his diet before admission, though not large, was not deficient in quality, and it was fortified by a milk-protein preparation rich in tryptophane, an amino-acid converted in the body to nicotinamide. Vitamin production in the intestine, however, may have been deficient owing to an alteration in the bacterial flora brought about by the courses of streptomycin; and there may have been inadequate absorption, for diarrhœa had been present since the early stages of the disease.

Within three weeks of starting a course of isoniazid he developed symptoms and signs of gross nicotinic-acid deficiency. During this time the only other drugs he was having were quinalbarbitone ('Seconal'), intravenous iron, and a vitamin preparation not containing the B_2 group. It thus seems likely that the isoniazid was the direct cause of the pellagra.

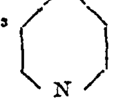
Pegum (1952) has suggested that isoniazid may block the action of nicotinamide by competitive inhibition. Other substances have been found which have this action (Woolley 1945, 1946). One of these, 3-acetylpyridine, and isoniazid are structurally similar to nicotinamide, differing from it in the side chain to the pyridine nucleus.



Nicotinamide



3-Acetylpyridine



Isoniazid

The amount of isoniazid which would compete successfully with nicotinamide in the formation of co-enzymes depends, by the law of mass equilibrium, on their relative concentration and their relative affinity for the co-enzyme residue.

As no previous case of fully developed pellagra has been reported during isoniazid therapy, its affinity is probably not great and its pellagra-producing effect depends on the patient's original nicotinamide level being low. Most patients develop a voracious appetite, and it may be that they are protected by the consequent high intake of B_2 vitamins. This patient was one of the minority whose appetite does not improve greatly. Exaggerated reflexes and difficulty in starting micturition are both found in some cases of pellagra, and it would be interesting to know whether the patients in whom these disorders developed during isoniazid therapy also had no improvement in appetite. Until further investigation has been carried out it may be advisable to give vitamin-B_2 complex to all patients taking isoniazid whose appetite remains poor.

SUMMARY

A man of 22 developed acute pellagra within three weeks of starting a course of isoniazid. It seems likely that the drug was directly responsible, and a theory of the mechanism is discussed.

We wish to thank Dr. Robert Coope for permission to report this case, and for his help in the preparation of this paper.

CONFUSIONAL PSYCHOSIS WITH RESIDUAL ORGANIC CEREBRAL IMPAIRMENT FOLLOWING ISONIAZID THERAPY

RICHARD A. HUNTER
M.D. Lond., D.P.M.
REGISTRAR, NAPSBURY HOSPITAL, ST. ALBANS

THE Medical Research Council report (1952) states that "isoniazid has shown little toxicity in the dosage used [200 mg. daily] over a three-months period," and that "toxicity with isoniazid has, so far, been a very minor problem." The side-effects reported in the M.R.C. trial were drowsiness in 8%, increase of deep reflexes in 13%, tremor of the limbs in 12%, twitching of the legs in 2 out of 173 patients, and difficulty in initiating micturition in another 2, with frequency in a 3rd. 9 patients suffered from constipation, 3 from transient flushing of the face, and 4 from skin disorders. There were 4 cases of "nervous reaction."

Robitzek and Selikoff (1952), using isoniazid in a dosage of 2–4 mg. per kg. and propyl isonicotinic acid hydrazide 2–10 mg. per kg. on 44 patients for up to fifteen weeks, found twitching of the extremities (37 cases) and increased deep reflexes (26 cases) to be the commonest signs of toxicity, followed by constipation, and vertigo associated with a fall in systolic blood-pressure. They concluded (Selikoff et al. 1952a) that the hydrazide of isonicotinic acid, and its glucoside and isopropyl derivatives, exert moderate "acute" side-effects related mainly to the central and autonomic nervous systems. Among the central-nervous-system effects they include hyperactive reflexes, involuntary twitching, insomnia, and drowsiness; the effect on the autonomic nervous system appeared to consist in sympathetic stimulation, as suggested by the constipation, bladder sphincter disturbance (delay of stream), and mouth dryness. Vertigo, when it occurred, was thought to be vasomotor in origin. Also noted were headache and disturbed vision. However, in a subsequent paper (Selikoff et al. 1952b) they attach little clinical importance to these manifestations of toxicity.

The higher incidence of toxicity reported by Robitzek and Selikoff (1952) may be explained in two ways.

1. Robitzek and Selikoff used doses up to 10 mg. per kg. body-weight, whereas the Medical Research Council employed a uniform dosage of 200 mg. per day. As 69% of the M.R.C. patients are described as being in fair or good condition, their average weight may be estimated at 8–10 st., and they were therefore receiving isoniazid in an estimated dose of 3–4 mg. per kg. daily, a rather lower amount than that employed by Robitzek and Selikoff.

2. All Robitzek and Selikoff's patients were suffering from acute progressive bilateral caseopneumonic tuberculosis, were losing weight, and were constantly pyrexial; the disease was considered far advanced and no longer suitable for any other standard accepted form of treatment. Of the M.R.C. series, only 31% of patients were in poor general condition, 44% being afebrile; only 29·5% had acute rapidly progressive pulmonary tuberculosis, 47·5% having "other forms of pulmonary tuberculosis suitable for chemotherapy."

The 4 cases of "nervous reaction" reported by the M.R.C. consisted in one patient of nausea and feeling nervy, in another of abdominal discomfort and a feeling of fright, and in a third merely of dizziness—these symptoms being limited to the first month of therapy. In the fourth patient showing a "nervous reaction," "isoniazid was stopped after two months because the patient was restless, irritable, had marked tremor of the hands and occasional spasmodic jerks and tics of the face and limbs, and finally had night wandering." No attempt was made to resume treatment, and "the symptoms gradually disappeared."

The following is an account of a case in which treatment with isoniazid for just over four months was followed by an acute toxic confusional psychosis, and by almost all the toxic manifestations previously reported. Eight weeks later the patient was left with residual organic cerebral impairment of the Korsakow type. The case is reported in detail because it seems to be the first in which such serious disturbances of the central nervous system have developed.

CASE-RECORD

Widow aged 41. Family history negative. No previous history of nervous or mental disease. Attacks of asthma during the summer for many years. She is described as having been bright, with a good memory, and a capable housewife; a non-smoker and teetotaller.

Pulmonary tuberculosis with positive sputum first diagnosed in 1938, when she received sanatorium treatment. She had a relapse in 1948 and since 1950 had lived quietly at home. Little improvement in 1951 after three months' treatment with *p*-aminosalicylic acid.

Treatment with Isoniazid

On April 28, 1952, she commenced treatment with isoniazid 50 mg. t.d.s., her weight being 7 st. (98 lb.). Two weeks later she had tingling in the arms and legs, which persisted throughout the time of taking the drug. By June she was losing weight and on July 28 the dose was doubled to 100 mg. t.d.s. In August she complained of insomnia and failing memory; later of feeling "funny in the head" and at times confused. These symptoms became worse and by Aug. 20 she could not remember the day of the week or write out a shopping-list.

Aug. 26 she spent crying, and the next day was agitated, used swear-words not previously her habit, and demanded that imaginary cats be removed. She continued to talk and behave strangely and by Aug. 29 she could no longer distinguish members of her family. On the following days she was more confused, would not be washed, and refused food and drink. She collapsed at midday and afterwards cried out for her mother who had been dead for many years. She appeared to be terrified and once rushed into the street saying she was frightened of strange men in the house.

On Aug. 31 she received the last dose of isoniazid. She no longer recognised anybody, was very agitated, got out of bed, and knocked on the walls; she still refused nourishment and no contact could be made with her. On Sept. 1 she complained that the light was too bright and insisted on curtains being kept drawn. She was removed to hospital, not having passed urine, opened her bowels, or slept for two days.

Condition on Admission to General Hospital

On admission, she did not answer questions, screamed as if in terror, and kept her eyes covered either with her hands or by burying her head under the bedclothes. She was disorientated for time, place, person, and situation. She was aurally hallucinated, conversing with imaginary people, and had visual hallucinations, seeing coloured lights, talking of "putting out the moon" and "sending the cats away." She was thin and pale with signs of bilateral pulmonary tuberculosis and clubbing of the fingers. No cardiovascular system abnormality apart from tachycardia. She showed irregular twitching of the face and extremities with jerky and exaggerated movements. No neck rigidity: Kernig's sign negative. Pupils equal, reactive to light. Cranial nerves appeared normal. Sensation could not be tested. Motor power seemed unimpaired; deep reflexes very brisk, plantar responses flexor. On Sept. 3 she was transferred on certificate to a mental hospital as she presented as a schizophrenic, catatonic type.

Observations in Mental Hospital

On admission her temperature was 99°F, her pulse-rate 94, and her respirations 22 per min. Heart sounds soft, blood-pressure 100/70. Bladder full to umbilicus, catheterisation producing 60 oz. urine. Weight 5 st. 12 lb. Findings in nervous system same as above plus a medium tremor of the extremities. She complained of headache and constipation, was totally disorientated, and could give no account of herself.

Laboratory investigations.—Hæmoglobin 10·0 g. per 100 ml. Red blood-cells 5,380,000 per c.mm.; marked microcytosis and hypochromia. White cells 16,650 (90% neutrophils, no eosinophils). Erythrocyte-sedimentation rate (Westergren) 7 mm. in one hour. Blood-urea 43 mg. per 100 ml. Wassermann and Kahn reactions negative. Cerebrospinal fluid normal. Sputum: tubercle bacilli present in large numbers. *Urine*: *light cloud of albumin. Radiography*: *skull, normal chest, multiple cavities and fibrosis both upper lobes.*

Course.—For the next eleven days she ran an irregular fever, up to 100°F, and the pulse, at times irregular, varied between 90 and 110, respiratory-rate between 28 and 34 per minute. She could not pass urine or open her bowels spontaneously and had to be catheterised daily.

She continued restless by day and night. She had to be spoon-fed. Her mouth was very dry and she developed sores at the corners. By Sept. 5 twitching of muscles was gross and resulted in head-banging and kicking movements which ceased in deep sleep and gradually subsided. She had visual hallucinations of cats and dogs on her bed and about the ward. She saw blood on the ceiling and similarly misinterpreted rust on water-pipes. At night she heard voices calling out.

By Sept. 10, one could have very brief periods of conversation with her. On the 16th she opened her bowels and passed urine spontaneously. She was much less restless, tremor and twitching had disappeared and reflexes were less brisk. By the 20th, though she felt exhausted, she was in fair contact with her environment, and no longer hallucinated, having sufficient insight to ask "Am I going mad?"

On Sept. 24 the hæmoglobin was 9·8 g. per 100 ml.; the red cells were 4,500,000 per c.mm., and the white cells 6200. E.S.R. 32 mm. in one hour. Blood-urea 32 mg. per 100 ml. A urinary infection which had developed was treated with sulphadimidine.

By the beginning of October her general condition had improved greatly despite unchanged chest signs. Temperature normal, pulse 75–95, respiration-rate 20–22 per min., blood-pressure 120/80. Eating and sleeping well. She remained quiet but complained of being confused and unable to remember. Progress was maintained and by Oct. 25 she had gained 7 lb. in weight.

Present Mental State

She is rather apathetic and does not speak unless addressed. She coöperates during examination, becomes anxious, but is easily reassured. She is fairly quick to answer questions, but frequently says "I don't know" and "Oh dear, I am so confused." She is emotionally facile, being easily moved from smiling to tearfulness. She is neither deluded nor hallucinated. She is orientated in so far as she knows the name of the hospital; but she cannot place it, nor does she know that it is a mental hospital. She does not know the time of day; she knows the day of the week and the year, but gives the date as March 7. She cannot distinguish the various nurses in the ward, and is not sure whether she has seen her regular doctor before. She gives a fair account of her early life, and knows her date of birth, but not the date of her marriage, nor her daughter's age. In describing events of the last ten years she loses the trend, cannot give them in consecutive order, and has no sense of time. Her memory for recent events is almost absent; she thought she had been in hospital for a day or two, could not tell how she got there, nor where she came from. She could not remember what she had read in the newspaper nor what she had eaten that day. Half an hour after her visitors had gone she complained of

There was little change in his condition at first, but after a week the stools increased from 3 to 6 per day and became very offensive. By Aug. 10 he had become very depressed and slightly irrational, and it was noticed that the dorsum of each hand was red and roughened. His mental condition deteriorated rapidly and by Aug. 15 he was refusing to eat. The diarrhœa had become more frequent, and on Aug. 17 he became incontinent of urine and fæces.

The next day isoniazid was stopped, and a psychiatrist who saw him reported that he was suffering from a schizophrenic reaction which presented many catatonic features. He had marked thought-blocking, incongruity between emotion and stimulus, ambivalence, sudden impulsive movements, and possibly hallucinations. On Aug. 20 he was worse, being quite irrational and possibly suicidal.

By now the redness on the dorsum of his hands was typical of pellagra, and it had spread symmetrically to above the wrists, where there was a sharp line of demarcation with the healthy skin. He also had cheilosis, redness of the nasolabial folds, and was incontinent of frequent watery stools.

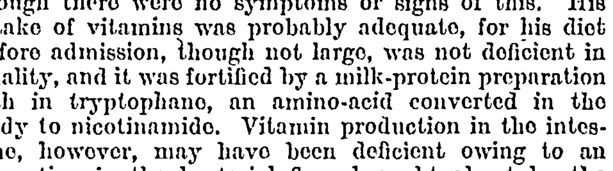
On Aug. 20 treatment was started with four-hourly doses of nicotinic acid, 40 mg. intramuscularly and 50 mg. by mouth, and vitamin-B complex intramuscularly twice daily. On Aug. 22 he was less disturbed mentally, he was able to take a high protein diet, and he was no longer incontinent, but still had much diarrhœa. By Aug. 24 his mental symptoms had all disappeared, the hand lesions were clearing, and the diarrhœa was less. By Sept. 1, the skin lesions had disappeared, and he was passing only 2 to 4 semiformed stools per day. His weight, which had remained at 112 lb. until Aug. 24, was now 120 lb. On Sept. 19 his weight was 131 lb. and he was only passing 1 or 2 semiformed stools per day, but the abdominal pains were still troubling him several times each day.

DISCUSSION

It is possible that on admission to hospital this patient was suffering from a deficiency of the B group of vitamins, though there were no symptoms or signs of this. His intake of vitamins was probably adequate, for his diet before admission, though not large, was not deficient in quality, and it was fortified by a milk-protein preparation rich in tryptophane, an amino-acid converted in the body to nicotinamide. Vitamin production in the intestine, however, may have been deficient owing to an alteration in the bacterial flora brought about by the courses of streptomycin; and there may have been inadequate absorption, for diarrhœa had been present since the early stages of the disease.

Within three weeks of starting a course of isoniazid he developed symptoms and signs of gross nicotinic-acid deficiency. During this time the only other drugs he was having were quinalbarbitone ('Seconal'), intravenous iron, and a vitamin preparation not containing the B_2 group. It thus seems likely that the isoniazid was the direct cause of the pellagra.

Pegum (1952) has suggested that isoniazid may block the action of nicotinamide by competitive inhibition. Other substances have been found which have this action (Woolley 1945, 1946). One of these, 3-acetylpyridine, and isoniazid are structurally similar to nicotinamide, differing from it in the side chain to the pyridine nucleus.



Nicotinamide 3-Acetylpyridine Isoniazid

The amount of isoniazid which would compete successfully with nicotinamide in the formation of co-enzymes depends, by the law of mass equilibrium, on their relative concentration and their relative affinity for the co-enzyme residue.

As no previous case of fully developed pellagra has been reported during isoniazid therapy, its affinity is probably not great and its pellagra-producing effect depends on the patient's original nicotinamide level being low. Most patients develop a voracious appetite, and it may be that they are protected by the consequent high intake of B_2 vitamins. This patient was one of the minority whose appetite does not improve greatly. Exaggerated reflexes and difficulty in starting micturition are both found in some cases of pellagra, and it would be interesting to know whether the patients in whom these disorders developed during isoniazid therapy also had no improvement in appetite. Until further investigation has been carried out it may be advisable to give vitamin-B_2 complex to all patients taking isoniazid whose appetite remains poor.

SUMMARY

A man of 22 developed acute pellagra within three weeks of starting a course of isoniazid. It seems likely that the drug was directly responsible, and a theory of the mechanism is discussed.

CONFUSIONAL PSYCHOSIS WITH RESIDUAL ORGANIC CEREBRAL IMPAIRMENT FOLLOWING ISONIAZID THERAPY

RICHARD A. HUNTER
M.D. Lond., D.P.M.
REGISTRAR, NAPSBURY HOSPITAL, ST. ALBANS

THE Medical Research Council report (1952) states that "isoniazid has shown little toxicity in the dosage used [200 mg. daily] over a three-months period," and that "toxicity with isoniazid has, so far, been a very minor problem." The side-effects reported in the M.R.C. trial were drowsiness in 8%, increase of deep reflexes in 13%, tremor of the limbs in 12%, twitching of the legs in 2 out of 173 patients, and difficulty in initiating micturition in another 2, with frequency in a 3rd. 9 patients suffered from constipation, 3 from transient flushing of the face, and 4 from skin disorders. There were 4 cases of "nervous reaction."

Robitzek and Selikoff (1952), using isoniazid in a dosage of 2–4 mg. per kg. and propyl isonicotinic acid hydrazide 2–10 mg. per kg. on 44 patients for up to fifteen weeks, found twitching of the extremities (37 cases) and increased deep reflexes (26 cases) to be the commonest signs of toxicity, followed by constipation, and vertigo associated with a fall in systolic blood-pressure. They concluded (Selikoff et al. 1952a) that the hydrazide of isonicotinic acid, and its glucoside and isopropyl derivatives, exert moderate "acute" side-effects related mainly to the central and autonomic nervous systems. Among the central-nervous-system effects they include hyperactive reflexes, involuntary twitching, insomnia, and drowsiness; the effect on the autonomic nervous system appeared to consist in sympathetic stimulation, as suggested by the constipation, bladder sphincter disturbance (delay of stream), and mouth dryness. Vertigo, when it occurred, was thought to be vasomotor in origin. Also noted were headache and disturbed vision. However, in a subsequent paper (Selikoff et al. 1952b) they attach little clinical importance to these manifestations of toxicity.

The higher incidence of toxicity reported by Robitzek and Selikoff (1952) may be explained in two ways.

1. Robitzek and Selikoff used doses up to 10 mg. per kg. body-weight, whereas the Medical Research Council employed a uniform dosage of 200 mg. per day. As 69% of the M.R.C. patients are described as being in fair or good condition, their average weight may be estimated at 8–10 st., and they were

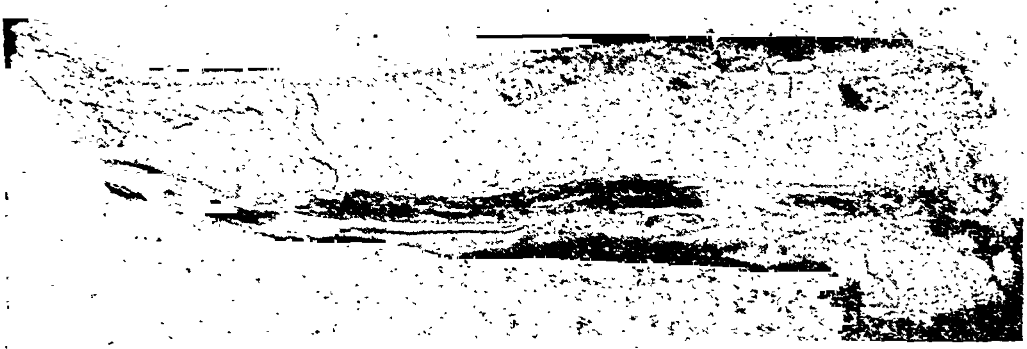

Fig. 1—Skin and subcutaneous fat from abdominal wall showing extensive fat-necrosis (× 1½).

he complained of severe pain in the region of the tendo Achillis and calf of the right leg. This was followed by the appearance on both legs of a crop of red-brown nodules which grew to a diameter of 2·5 cm. The differential diagnosis was then considered to lie between erythema nodosum and Bazin's disease, although the condition was typical of neither. Against erythema nodosum was the fact that the nodules were predominantly on the posterior aspects of the legs; against Bazin's disease was the absence of any tendency to ulceration.

A few weeks later the leg lesions were regressing, but a fresh crop of nodules appeared beneath the skin of the trunk and limbs. The patient's arms and legs felt stiff, and he complained of severe pains like toothache "deep in the bones of both legs." This caused him difficulty in walking. He had lost his appetite and a little weight but still did not look ill.

Condition on Admission

Admitted to hospital on Jan. 21, 1951, he was slightly pale and had bilateral palmar erythema, which he declared had been present as long as he could remember. Multiple subcutaneous nodules were present. In the skin of both calves their colours were those of fading bruises. On the trunk (anteriorly and posteriorly), thighs, upper arms, and scalp there was no discoloration except where the lesions had become attached to the skin, where they were dusky bluish red. The nodules varied from 0·5 to 2·5 cm. in diameter but gradually increased in size and a few were tender.

Biopsy

The nodule was broken in the course of removal, and its interior resembled pus. It proved to be a non-specific granuloma notable for the high degree of necrosis in contrast to the comparatively slight cell reaction. Samples of pus from the nodule, from a skin abscess, and from the right elbow-joint were all sterile on culture, but were remarkable for showing a paucity of cells in contrast to the large amount of necrotic material, and an excess of fat-globules which dissolved in ether.

Investigations

White-cell counts showed a gradually rising polymorph leucocytosis, with an eosinophilia in the first count which subsequently disappeared. Thus on Nov. 21 there were 10,900 white cells per c.mm. (polymorphs 65%, eosinophils 17%); on Nov. 29, 15,000 white cells per c.mm. (polymorphs 88%, eosinophils 0·5%); and on Feb. 13 20,800 white cells per c.mm. (polymorphs 89%, eosinophils 1·5%). A red-cell count showed 3,300,000 per c.mm., Hb 55%. The amount of alkaline phosphatase was increased (45 King-Armstrong units). Radiography showed only localised periosteal new-bone formation at the upper end of the left tibia.

Course of Illness

About ten days after admission the patient complained of pain in the right elbow, which restricted all its movements. There were nodules on the medial and lateral aspects of the joint, and it was difficult to tell whether a true arthritis was present. In the next few days these nodules became fluctuant, and could apparently be reduced into the joint; fluctuation could be elicited from one nodule through to another. The joint then became painless and the movements full except for slight limitation of extension. Meanwhile nodules elsewhere had grown larger, and most of them had gained attachment to the skin and become fluctuant. They were most numerous in areas of pressure, such as the back. A few on the left hip and heel came to resemble abscesses about to rupture through the skin. Most of them remained painless and not tender.

The patient had irregular pyrexia, up to 102°F, which did not respond to antibiotics. His urine occasionally contained small quantities of albumin. The fluctuating nodules, especially those on the back and over pressure points, showed a distinct tendency to coalesce. The patient perspired profusely. He finally developed acute dilatation of the stomach and died on Feb. 22, 1951.

NECROPSY

There was considerable general wasting. The subcutaneous fat formed nodular masses all over the body, especially on the back, where they were large, irregular, and firm in consistence. In some regions—notably the right costal margin, both elbow-joints, and the proximal interphalangeal joint of the left ring finger—the swellings were fluctuant and contained a creamy fluid, grey and granular from the costal margin, and green and smoother from the right elbow-joint.

The skin had a sallow almost icteric tinge, but the scleræ were not yellow. The lymph-nodes, except those in the mesentery, were not enlarged. On section the subcutaneous fat of the chest, abdomen (fig. 1), both legs, and the right arm was seen to be copiously flecked with fluffy white areas of fat-necrosis 3–5 mm. in diameter. Much less frequent, but still numerous, were small abscess-like collections of white, grey, or green creamy fluid: these varied in size from 5 mm. to several centimetres and were irregular in shape.

The calvarium was of normal average thickness and the diploë was pink. The meninges and venous sinuses were normal. The brain was pale but otherwise appeared normal. The cerebral vessels were slightly atheromatous.

Abdomen

There was no free fluid in the peritoneal sac, and the peritoneum was smooth and shiny. The stomach was dilated and empty except for a few ounces of bright-green fluid. There were a few calcified lymph-glands in the mesentery but no sign of fat necrosis in the mesenteric or retroperitoneal fat. The liver was enlarged, weighing 2830 g. On section it was generally brownish yellow and felt greasy, and it contained numerous tumours varying in appearance from white-solid masses to pink soft gelatinous ones. Round the smaller secondary deposits the liver tissue appeared to be compressed, but round the large pink areas it was gelatinous. There were numerous deposits under the capsule. Occasionally the secondary masses were completely necrotic. Here and there, remote from the tumour masses, the liver showed small grey flecks of necrosis. The biliary system appeared normal.

A large tumour occupied the centre portion of the pancreas; it was irregular in shape, fluctuant, and largest in the middle, tapering away towards the head and tail (fig. 2). The outer surface of the pancreas was smooth and covered by peritoneum. On section were found numerous thick-walled loculated cysts surrounded by considerable fibrosis; some contained serous fluid, some contained thick creamy fluid, and others were solid. Between the cysts the tumour tissue was white and soft, with necrotic areas green or pink in colour and usually gelatinous. The tumour was poorly demarcated from the pancreas, especially towards the tail. The head of the pancreas was moderately firm, and the pancreatic duct, though tortuous, could be traced through the tumour and was patent throughout. There was a considerable amount of adipose tissue in and around the gland, and in the region of the tail there were one or two very small foci of fat-necrosis.

Both kidneys (left 190 g., right 230 g.) showed one or more small congenital cysts but were otherwise normal. The prostate showed senile enlargement.

Other Findings

The bone-marrow, ribs, sternum, and vertebral bodies appeared normal. The right humerus, femur (fig. 3), and not having had any. Pressed to remember recent events, she confabulates to a marked degree and is readily led to enlarge on details. She could not remember a name and address for five minutes, but could repeat five digits forwards and three backwards. Told to repeat the substance of a short story she could only remember that the principal character was a cowboy and that a dog came into it. She subtracted 7 from 100 with only one mistake, but could not multiply 7 by 9 or 3 by 17 accurately. She could not remember the dates of the first world war and thought the Prime Minister was Mr. Attlee. She knew the Queen's name, but not that of her husband or children. Asked to name six large cities in England, she gave London, Swansea, Liverpool, Sunderland, Liverpool, and Swansea, with much hesitation. Her interpretation of proverbs was satisfactory, and she succeeded on a short list of similarities and differences.

Psychological Tests

On the Shipley Hartford Retreat Scale she scored 30 out of 40 in the vocabulary test, but only 4 out of 20 in the abstraction test. This gives a vocabulary age of 17 years, an abstraction age of 9·9 years; and a conceptual quotient of 58 which, on this scale, is to be regarded as definitely pathological and indicative of organic cerebral impairment.

On the Mill Hill Vocabulary Scale (form 1 senior) she scored a total of 61 out of 88, and on the Progressive Matrices Test 27 out of 60. She is therefore verbally of average ability, her score lying at the 60th percentile for people of her age. On the matrices her score only puts her in the 25th percentile.

These tests confirm the clinical finding of considerable organic cerebral damage.

DISCUSSION

Although Thomson (1952) mentions transient loss of memory as one of the toxic manifestations of isoniazid, the only confusional state reported is the mild one in the M.R.C. report, quoted in detail above. Their patient showed only restlessness, irritability, and night wandering, and these gradually disappeared when treatment was stopped after two months. Our patient showed the toxic manifestations previously reported to a marked degree. It is estimated that she received isoniazid in a dose of 3·5–5 mg. per kg. body-weight daily in the first three months, the only toxic manifestations being paræsthesia and loss of weight. The dose was then doubled and, in view of progressive weight loss, may be estimated at 8–10 mg. per kg. Two weeks later she developed insomnia, loss of appetite, confusion, and loss of memory; but treatment was continued for another fortnight during which she developed retention of urine, constipation, tachycardia, fever, photophobia, and a toxic confusional psychosis with tremor, twitching of muscles, and hyper-reflexia. On account of disorientation, bizarre behaviour, and hallucinations, she gave the impression of acute catatonic schizophrenia. Tuberculous meningitis was excluded by the absence of signs of meningitis and normal cerebrospinal fluid.

Increased sensitivity to light and colours as shown by this patient is similar to the experience given in a letter to THE LANCET (1952) which mentions being uncomfortably aware of physical surroundings: and "the trees seemed greener and the sky bluer." Visual disturbances were also noted by Selikoff et al. (1952a). Her present mental state also points to the diagnosis of an organic reaction. Although sensory disturbances could not be demonstrated objectively, the existence of paræsthesia, tremor, muscular twitching, and hyper-reflexia suggest a toxic neuropathy during the acute phase. Taken in conjunction with the acute mental symptoms and her present deficient memory for recent events, confabulation, and disorientation in time more completely than for place or person, as well as emotional deterioration shown by increased suggestibility and emotional facility, make the diagnosis of Korsakow's psychosis certain. Further proof is afforded by her performance on psychological tests.

Cases of Korsakow's psychosis may run a long course, with greater improvement physically than mentally. As the condition is the result of organic damage to the nervous system many cases never recover fully, particularly in regard to memory, affectivity, and judgment. Our patient showed most improvement in the first four weeks while emerging from the acute phase. There has been little improvement since then. Physically she may be considered as back to her original condition before the episode here reported; mentally she remains impaired.

Could cerebral damage have been avoided had the drug been omitted earlier at the first onset of severe symptoms? Rubin et al. (1952) conclude that the two outstanding manifestations of isoniazid toxicity in dogs—namely, damage to the liver and the nervous system—may be reversible "upon prompt cessation of drug administration." When isoniazid was eventually discontinued our patient failed to improve and her physical and mental condition deteriorated for another week.

The confusion and impairment of memory which appeared in this case before other gross signs of toxicity may, in retrospect, be taken as danger-signals of cerebral damage.

SUMMARY

A woman of 41 with chronic bilateral pulmonary tuberculosis received domiciliary treatment with isoniazid, in a dose of 3·5–5 mg. per kg. body-weight for three months. During this time she developed tingling feelings in the extremities and lost weight. The dose was then doubled to 8–10 mg. per kg. daily for another month. Early signs of involvement of the central nervous system were confusion and loss of memory, followed by insomnia and anorexia. She developed a toxic confusional psychosis and later dryness of the mouth, retention of urine, constipation, tremor, muscular twitching, hyper-reflexia, and a microcytic hypochromic anæmia. Eight weeks later she was left with signs of organic cerebral impairment of the Korsakow type.

I wish to thank Dr. J. H. Patterson for encouragement and Dr. James A. Robertson for his interest and advice.

MANCHESTER ROYAL INFIRMARY

THIS case is reported because it presented a difficult diagnostic problem. A tumour of the pancreas and its secondaries in the liver retained some at least of the physiological activity of the normal pancreas and presented a pathological and clinical picture recorded in four other cases.

CASE-RECORD

A well-built man, aged 59, noticed in October, 1950, painless red firm flat nodules in the skin of both legs below the knees. After ten days these faded, but soon afterwards and the bone itself appeared unchanged. Outside the bone, next to the periosteum, there were scattered foci of fat-necrosis, some of which were surrounded by a few round cells indistinguishable from lymphocytes. There was no evidence of secondary tumour cells in serial sections of blocks taken from several areas. The red bone-marrow from the sternum appeared to be normal except for occasional isolated fat-cells showing early necrosis. No evidence of osteoporosis was obtained when the stripped femur was radiographed.

Other Organs

The *lungs* showed diffuse œdema, congestion, emphysema, purulent bronchitis, and a terminal bronchopneumonia. No evidence of secondary tumour was seen.

Frozen sections of the *brain*, stained by the methods of Loyez and Smith and Quigley, showed no evidence of demyelinisation in the many areas examined in this way. The *pituitary, suprarenals, thyroid, prostate, bladder, aorta,* and *heart muscle* were all normal. The *kidneys* were normal except for some œdema.

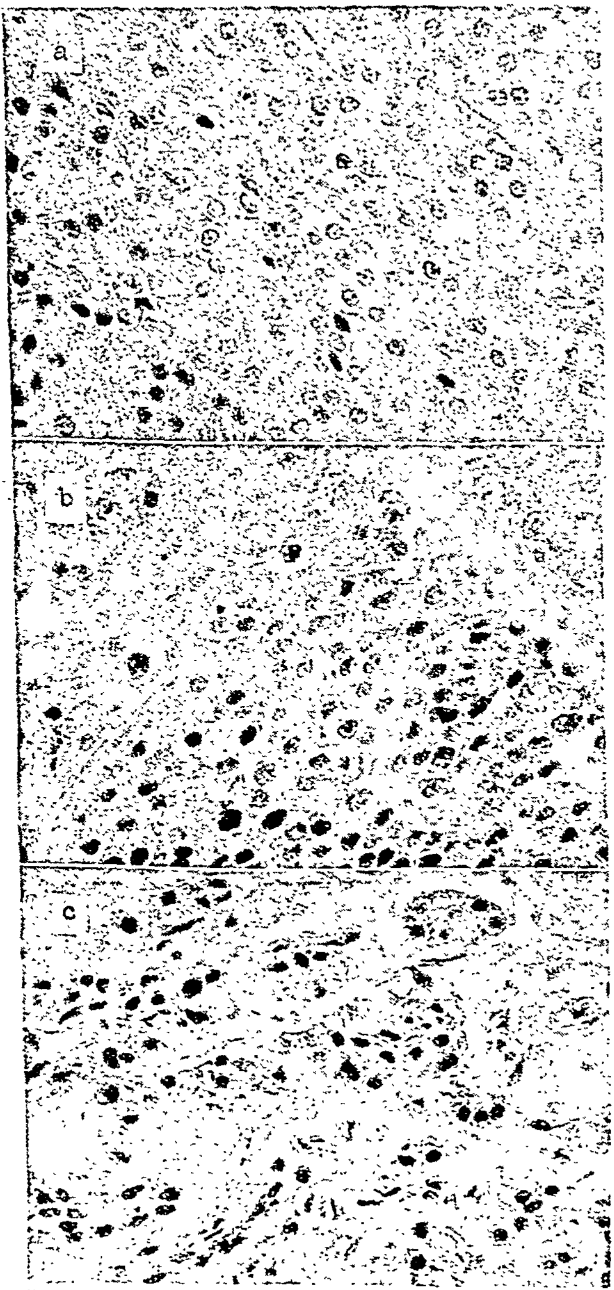

Fig. 4—Sections of tumour of pancreas showing various degrees of differentiation (× 480).

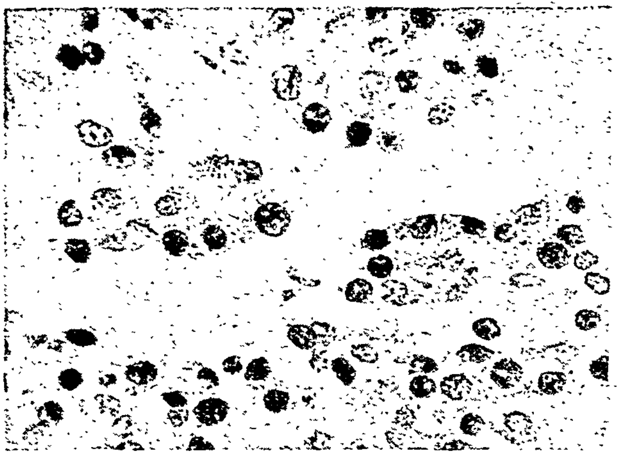

Fig. 5—Section of secondary deposits in liver, showing greater differentiation than in primary tumour shown in fig. 4*b*. Liver secondaries were producing much more lipase than was the primary tumour (× 480).

BIOCHEMISTRY

Semi-solid material from an "abscess cavity" contained neutral fat 21%, free fatty acid 19%, soaps 15%, cholesterol 1%, and debris 44% of dried weight. The serum-lipase level was 32 units per ml. Tissue lipase gave the following figures:

Pancreas:	tumour-free ..	*1200 units per g.
	tumour	1000 ,, ,,
Liver:	tumour-free ..	*300 ,, ,,
	tumour (secondary)	2400 ,, ,,

*As judged macroscopically.

Determination of Lipase

The method used for determining the lipase content of the tissues and blood was essentially that of Cherry and Crandall (1932). In this the substrate used is olive oil (triolein), digestion is for twenty-four hours, and the fatty acids produced are titrated with *N*/20 sodium hydroxide. Each unit corresponds to 1 ml. of *N*/20 sodium hydroxide required for this titration. The techniques used were:

Tissues.—About 3 or 4 g. of fresh tissue was cut up and ground with sand and about 50 ml. of physiological saline solution and then allowed to stand in the refrigerator overnight. The liquid extract was separated, and dilutions were put up so as to determine the volume of extract required to produce a final titration of about 3 ml. This is necessary to obtain comparable results, since enzyme activity does not increase in proportion to the amount of enzyme present. This effect is illustrated in the diagram (fig. 6). As a result, higher titrations do not adequately reflect the actual amount of enzyme present. The result was then expressed as the units per gramme of wet tissue calculated as follows:

$$\text{Units per gramme} = \frac{\text{ml. titration} \times \text{volume of extract} \times \text{dilution of extract}}{\text{weight of tissue used}}.$$

Normal post-mortem pancreases and livers were examined in the same way to determine the approximate normal range by the technique used. The results obtained were:

Pancreas:	1110–9000 (12 specimens) Average 4600 units per gramme.
Liver:	10–460 (10 specimens) Average 190 units per gramme.

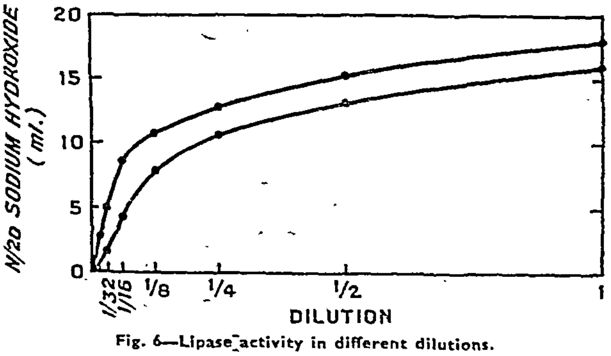

Fig. 6—Lipase activity in different dilutions.

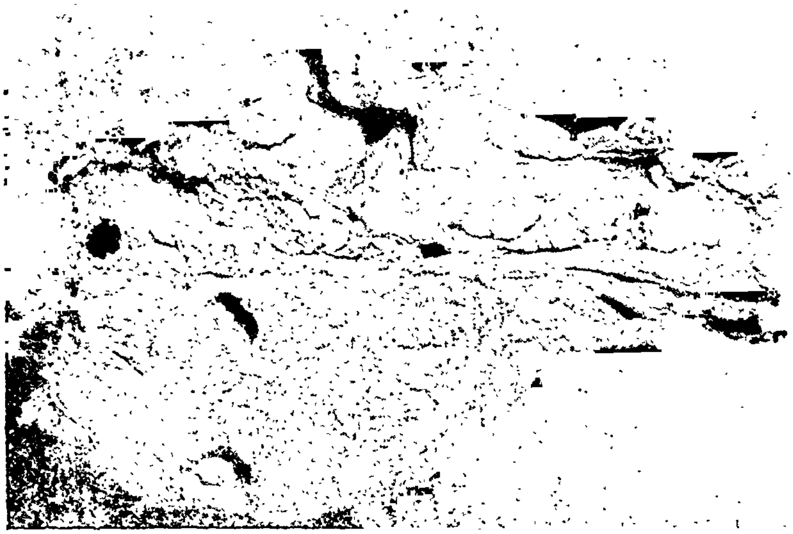

Fig. 2—Tumour in middle third of pancreas (about 4/5 of actual size).

tibia were sawn longitudinally and their marrow was uniformly grey and necrotic. The right elbow-joint was continuous with the subcutaneous abscess cavity already described, and the articular surfaces were roughened. The muscles, all other organs, and tissues appeared to be normal.

HISTOLOGY

Pancreas

The head and tail of the pancreas showed general patchy overgrowth of the connective tissue (fig. 4) and in some of the more fibrous areas there was evidence of duct proliferation. The parenchyma showed some patchy atrophy, with moderate infiltration by lymphocytes and plasma cells. The main ducts appeared to be normal, but the duct radicles in the head were slightly dilated. Many of the ducts contained eosinophilic material. Occasional areas of apparent necrosis were seen which showed no significant cell reaction, and some at least may have been due to post-mortem change. The islet tissue was normal. Adipose tissue in the tail region contained occasional areas of fat-necrosis. Here the fat-cells had a granular cytoplasm and looked opaque and the surrounding tissue was sparsely infiltrated with small round cells. No tumour tissue was seen in either head or tail. The body of the pancreas was wholly replaced by tumour tissue, which at its periphery sent thick finger-like projections of tumour into the surrounding pancreatic tissue and was surrounded by a dense fibrous reaction, which formed an imperfect capsule for the tumour. The tumour was made up of sheets of eosinophilic cells, divided by a delicate filamentous stroma into indistinct lobules. There was a fairly general differentiation into indefinite acini. Nuclear staining was variable and tended to be hyperchromic. The nuclei tended to be round, fairly uniform in size, and with one rather indistinct nucleolus. Occasionally the nuclei tended to elongate and the cells to form a palisade. The cells were polygonal, with a moderate amount of cytoplasm, and both nucleus and cytoplasm often showed vacuolation. Areas of necrosis occurred throughout the tumour. In the interstitial adipose tissue fat-necrosis was widespread.

Regional *lymph-nodes* showed mild subacute inflammation, with here and there occasional secondary deposits.

Liver

The metastatic deposits in the liver were better differentiated than in the primary growth (fig. 5). The cells were arranged in acinar circlets, though without a central aperture. Neither in the primary tumour nor in the metastases were zymogen granules seen.

There was marked perilobular fatty change in the liver cells, together with deposits of tumour tissue. Remote from the tumour deposits, scattered haphazardly, were small foci of necrotic liver cells surrounded by congestion and hæmorrhage. The cells in these foci and in the fatty areas showed masses of anisotropic crystals when viewed by polarised light. These areas took up copper acetate (Benda's stain) and were presumably areas of fat-necrosis.

Skin

The cutaneous lesions varied in appearance, shape, and size, but also showed fat-necrosis. They were mostly confined to the subcutaneous tissue, and only occasionally did they encroach on the dermis. The well-marked distinction into two types of lesion seen macroscopically was lost microscopically. The slightest lesion was a granular opacity of single or several contiguous cells.

Stained with hæmatoxylin and eosin, the cytoplasm was purple and appeared granular or faintly reticular in the adipose net. This change excited no response from the surrounding tissue. Occasionally in the region of these groups of cells small venous channels were thrombosed. In some of these small groups and in the larger lesions the altered fat-cells sometimes became smaller and crowded together, thus forming a more compact tissue, which might include some of the fibrous trabeculæ and vascular bundles. The limits of these areas were marked by a fairly vigorous fibroblastic and capillary extension, with a very slight infiltration with polymorphs, most of which showed necrosis. Scattered throughout these lesions were foci of disintegrating and disintegrated tissue, which might be basophilic or eosinophilic, reticulate or amorphous. The small arteries and veins present in some of these lesions showed necrosis; the walls of the arteries appeared hyaline and eosinophilic, and those of the veins, which usually contained thrombus, were sometimes infiltrated with polymorphs. Hæmorrhages from these necrotic vessels were only occasionally seen.

Although many blocks from the subcutaneous tissue of the chest and abdomen were sectioned serially and examined, nowhere was there any evidence of tumour cells or of any cells which might have been tumour cells but had disintegrated. All that could be seen were the lesions described above and scattered collections of lymphocytes, some round these lesions and others in the surrounding fat, often near to small vessels.

The semi-liquid material from the necrotic areas, when suspended in water, contained numerous needle-shaped crystals floating freely in the fluid, and heavier amorphous material. The crystalline material was anisotropic, but not the amorphous material. Material from the more solid areas of typical fat-necrosis emulsified badly, possibly owing to the absence of soaps, but had substantially the same constitution microscopically. The skin lesions appeared therefore to be areas of fatty and connective-tissue necrosis associated with venous thrombosis and vascular necrosis. There was no evidence of secondary deposits.

Bone

There was extensive necrosis of the bone-marrow of the long bones, essentially the same as that seen in the subcutaneous tissues. The fat-cells were granular and, when examined by polarised light, were seen to contain masses of anisotropic crystals. There was no inflammatory cell reaction

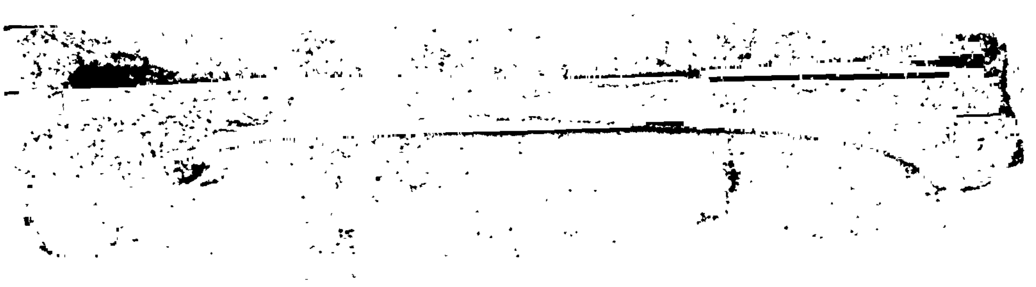

Fig. 3—Sawn femur showing fat necrosis.

and the bone itself appeared unchanged. Outside the bone, next to the periosteum, there were scattered foci of fat-necrosis, some of which were surrounded by a few round cells indistinguishable from lymphocytes. There was no evidence of secondary tumour cells in serial sections of blocks taken from several areas. The red bone-marrow from the sternum appeared to be normal except for occasional isolated fat-cells showing early necrosis. No evidence of osteoporosis was obtained when the stripped femur was radiographed.

Other Organs

The *lungs* showed diffuse œdema, congestion, emphysema, purulent bronchitis, and a terminal bronchopneumonia. No evidence of secondary tumour was seen.

Frozen sections of the *brain*, stained by the methods of Loyez and Smith and Quigley, showed no evidence of demyelinisation in the many areas examined in this way. The *pituitary, suprarenals, thyroid, prostate, bladder, aorta,* and *heart muscle* were all normal. The *kidneys* were normal except for some œdema.

Determination of Lipase

The method used for determining the lipase content of the tissues and blood was essentially that of Cherry and Crandall (1932). In this the substrate used is olive oil (triolein), digestion is for twenty-four hours, and the fatty acids produced are titrated with $N/20$ sodium hydroxide. Each unit corresponds to 1 ml. of $N/20$ sodium hydroxide required for this titration. The techniques used were:

Tissues.—About 3 or 4 g. of fresh tissue was cut up and ground with sand and about 50 ml. of physiological saline solution and then allowed to stand in the refrigerator overnight. The liquid extract was separated, and dilutions were put up so as to determine the volume of extract required to produce a final titration of about 3 ml. This is necessary to obtain comparable results, since enzyme activity does not increase in proportion to the amount of enzyme present. This effect is illustrated in the diagram (fig. 6). As a result, higher titrations do not adequately reflect the actual amount of enzyme present. The result was then expressed as the units per gramme of wet tissue calculated as follows:

$$\text{Units per gramme} = \frac{\text{ml. titration} \times \text{volume of extract} \times \text{dilution of extract}}{\text{weight of tissue used}}.$$

Normal post-mortem pancreases and livers were examined in the same way to determine the approximate normal range by the technique used. The results obtained were:

Pancreas:	1110–9000 (12 specimens) Average 4600 units per gramme.
Liver:	10–460 (10 specimens) Average 190 units per gramme.

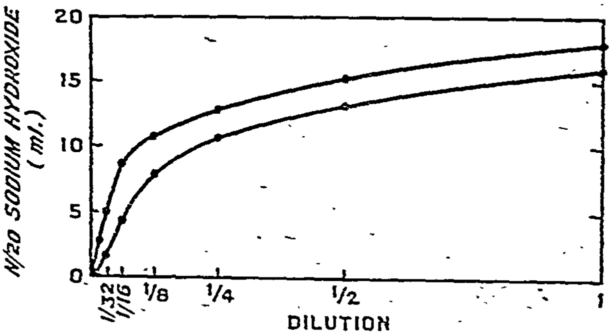

Fig. 6—Lipase activity in different dilutions.

Further work on the determination of the lipase activity of the pancreas is being done. These results must be regarded as provisional but suffice to show the relative degree of activity of the tissues from the present case.

Serum.—The lipase activity of the serum was also determined by the Cherry and Crandall method but modified so as to obtain a final titration of about 3 ml. With this a value of 32 units per ml. was obtained. This corresponds to a titration of approximately 11 ml. using 1 ml. of undiluted serum incubated for twenty-four hours. A series of post-mortem sera was also examined for lipase activity and these were found to be within the normal range for the Cherry and Crandall method, that is, less than 1·5 units.

DISCUSSION

Clinical Features

The present case and the four previously published present a clinical picture which is almost a definite entity. The features which tend to recur are:

1. Skin lesions, usually on the legs, which resemble erythema nodosum or Bazin's disease yet are typical of neither condition.
2. Subcutaneous nodules which later break down and become abscesses.
3. Limb pains and a tendency for the necrotic process to involve the joints.
4. A tendency to eosinophilia.
5. Sooner or later most of the patients develop malaise, high fever, and wasting, although they often remain in good condition for a time.
6. The duration of the illness is normally measured in months.

Pathology

The outstanding feature of this case was the occurrence of foci of typical fat-necrosis predominantly and strikingly in the subcutaneous tissue and in the yellow bone-marrow, with minor but similar changes in the tumour itself, the liver, the red bone-marrow, and the immediate locality of the long bones. Other workers have described a variable distribution. Auger (1947) found fat-necrosis of the renal capsule, the bladder, prostate, mesentery, heart, pancreas, subcutaneous tissue, and elsewhere, but did not record changes in the bone-marrow. Titone (1936) described necrosis in the subcutaneous tissue, lungs, muscle, and bone-marrow; Hegler and Wohlwill (1930) in the subcutaneous tissue and yellow bone-marrow; and Berner (1907) in the subcutaneous tissue as well as in the tumour. In all these cases the subcutaneous fat was involved, and the lesions there were widespread and histologically similar—namely, fat-necrosis of varying age accompanied by a variable cell reaction which increased with the age of the lesion. In no case was there positive evidence of the existence of secondary tumour cells related to the subcutaneous fat-necrosis. In three cases the bone-marrow was involved, and in one of these (Hegler and Wohlwill 1930) evidence of secondary deposits was found. Auger's (1947) case alone showed necrosis in most of the depot areas. Evidence of fat-necrosis in solid organs was found in Titone's (1936) case and in the present one. Here also it is notable that the liver showed fatty degeneration in areas remote from the tumour deposits, and it appeared to be the cells affected by this change that had undergone fat-necrosis. The histological appearance of these areas resembled that described by Schiller (1941). We feel justified, therefore, in concluding that the focal lesions described in the liver are areas of fat-necrosis. In Titone's case it is not clear that the necrosis was of fatty tissue. In our case the only evidence of fat-necrosis of the red bone-marrow was in the fat cells. The relationship of areas of fat-necrosis to necrotic vessels was emphasised by Auger, particularly in the mesentery, perirenal, pelvic, and other regions, but not in the skin. In the present case vascular necrosis and thrombosis were seen in association with the lesions in the subcutaneous fat.

Morphological evidence of functional activity of the tumour, shown by the presence of zymogen granules, was seen in Auger's case but not in ours and was not described in the others. It is well recognised that tumours and their secondary deposits when well differentiated may retain some or all of the functional activities of the parent tissues. This is particularly true of tumours of the endocrine system. It is also seen elsewhere, as in mucus-producing adenocarcinoma and bile-producing hepatomas. Ewing (1940) gives evidence of chemical function in tumours and notes that activity fades with increasing anaplasia. In the present case we found chemical evidence that the tumour and its secondaries were producing large amounts of lipase up to the time of death.

High serum-lipase levels were noted in 40·5% of cases of carcinoma of the pancreas reviewed by Comfort and Osterberg (1940). That this is not necessarily associated with tumour activity is shown in the experimental ligation of the pancreatic ducts in dogs and by the raised serum-lipase in acute pancreatitis in man (Comfort et al. 1943). The explanation given is that obstruction of the pancreatic ducts leads to rupture of their radicles under the stress of pent up secretion, which is released via lymphatics into the blood-stream. In these circumstances the effect is transient and disappears as the gland atrophies. The highest value for serum-lipase obtained by these workers was 15·8 ml. of *N*/20 sodium hydroxide per ml. of serum in a case of carcinoma of the pancreas. A level of 9·7 ml. recorded earlier in the same patient led them to suggest functional activity of the tumour, though there was possibly the complication of previous pancreatitis and duct obstruction. Chemical investigation of the tissues five days after death did not establish this activity but did not discount its possibility.

The problem in our case was to decide whether the remarkable fat-necrosis observed was due to small active secondaries which, by secreting lipase, underwent autodigestion and produced surrounding fat-necrosis, or whether it resulted from the high serum-lipase in combination with other factors, such as vascular thrombosis and trauma. There was also the problem of the distribution of the fat-necrosis—its peculiar tendency to occur predominantly in the subcutaneous fat and in the yellow bone-marrow. We do not know of any difference in the chemical constitution of the fat in these regions compared with that elsewhere which would make it especially susceptible to the action of lipase, and we can offer no explanation for this phenomenon.

Hegler and Wohlwill (1930) were satisfied that active secondaries were responsible for the fat-necrosis they described; Poičić (1920) suggested that this was also the explanation in Berner's patient, and Titone (1936) came to the same conclusion in his case but could not demonstrate such deposits. Auger (1947), however, could find no evidence of secondary deposits related to fat-necrosis, and we have had a similar experience. Thus in only one of the five cases reported so far has any evidence of secondary tumour in close relation to the fat-necrosis been found, and then only in the bone-marrow, where the association may well have been fortuitous.

We agree that, when secondary deposits of lipase-producing tissue occur in fatty regions, necrosis may be expected to develop, but we suggest that fat-necrosis can also occur from high serum-lipase levels alone in the absence of such metastases. Whether accessory factors, such as vascular thrombosis and trauma, must also be present we do not know.

Distant foci of fat necrosis have been found experimentally and in acute pancreatitis with duct obstruction (Perry 1947). His experimental work suggested that they were due to lymphatic spread of lipase. As the lymphatics drain ultimately into the blood-stream, generalised subcutaneous lesions could imply simply the further drainage of lipase into the general circulation. Lipase does not require very precise conditions for its activation; normal tissues have been shown to be adequate (Schiller 1941). The focal nature of the necrosis leads one to suspect some kind of directing influence, such as the vascular system. Auger showed that necrotic vessels were fairly constantly associated with the foci of necrosis, and in the present case necrosis of small vessels and thrombosis of venules were seen in association with the subcutaneous lesions, but we could not decide whether these antedated the necrosis or were a part of it. Multiple venous thromboses tend to occur in some types of neoplasia, especially in carcinoma of the pancreas (Sproul 1938). Possibly thromboses of this kind in association with high lipase values may initiate the foci of fat-necrosis.

The part played by trauma is difficult to assess. It might reasonably be thought to be a factor in the production of the subcutaneous lesions, but it is hard to believe that it could have played any part in the lesions of the bone-marrow, where one would have thought the fat was exceptionally well protected. Berner (1908), who thought that trauma did explain the skin lesions, advanced no evidence in support. In the present case, however, we noted that the lesions were much larger and more obvious over the pressure points and on the dorsum of the body, suggesting that it did contribute something to the genesis of the necrosis.

SUMMARY

A case is reported of adenocarcinoma of the body of the pancreas with secondary deposits in the liver only, associated with widely disseminated fat-necrosis in the subcutaneous tissues and bone-marrow.

This disseminated fat-necrosis produced a striking clinical picture constituting a difficult diagnostic problem.

The tumour and its secondaries were functionally active and were producing lipase in considerable quantities. The resulting high serum-lipase level seems to have been the cause of the disseminated fat-necrosis in the subcutaneous tissues and in the bone-marrow. Venous thrombosis, vascular necrosis, and trauma were possible accessory factors in the production of the necrotic lesions.

In cases presenting similar clinical features estimation of the levels of pancreatic enzymes in the serum during life may assist the diagnosis.

We are indebted to Dr. William Brockbank for his help and permission to publish the clinical records of this case; to Prof. A. C. P. Campbell for his encouragement and advice; to the steward and technicians of the department of pathology for their coöperation; and to Mr. F. W. Barnes for his assistance with the biochemistry. A special word of thanks is due to Dr. Sabina Strich for her considerable help with the translations from the German papers.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Effects of Intense Sound

ON Nov. 7 Air Vice-Marshal E. D. D. DICKSON was inducted as president of the section of otology of the Royal Society of Medicine. In a presidential address he discussed Effects of Intense Sound and Ultra-Sound on the Ear.

The human ear, he said, appreciates sounds of frequencies ranging from 20 to 20,000 cycles per second—from about the bottom note on a piano to more than two octaves above the top note. These are known as the sonic frequencies. Ultrasonic frequencies are those above 20,000 cycles per second; the term "supersonic" refers to speeds above those of sound. The sound-wave travels at about 760 miles per hour.

Intense sound can be defined as one that is strong enough to be perceived by structures other than the ear itself. In clinical audiology the normal unit of intensity is the decibel. The President gave some examples of noise in everyday life: a whisper has an intensity of up to 30 decibels; normal conversation, or a quiet motor-car, between 35 and 55 decibels; the raised voice, or a railway sleeping-car, between 60 and 75 decibels; and a shout about 100 decibels. At an intensity of 120 decibels the human ear experiences discomfort. It is already possible to measure intensities of noise at sonic levels, and equipment is now being developed in the Royal Air Force to measure the intensity of ultrasonic frequencies.

The sensation of loudness depends on the frequency and intensity of the sound. Acoustic trauma is influenced by many factors: the total time of exposure to noise, the duration of each exposure, the frequency of the noise, its volume, the use of protective devices, the age of the person exposed, and the presence or absence of previous aural disease.

A noise of more than 90 decibels' intensity may cause acoustic trauma. There are two types—the explosive and the chronic. The explosive type results from exposure to a sudden loud noise giving rise to acute concussion of the inner ear; there is permanent loss of hearing for sounds of all frequencies, and especially the higher ones. The chronic type of acoustic trauma is caused by long-continued exposure to noise, particularly from sounds of high frequency; interrupted sounds cause more damage than continuous ones, and the loss of hearing affects only frequencies above that of the damaging sound. This type of hearing loss is reversible if exposure is stopped, but with a loss of 60 decibels return to normal hearing may take four or five days.

Among flying personnel the tendency to deterioration in hearing is greater from multi-engined than from single-engined aeroplanes. In piston-engined aeroplanes the noise is mainly of low or middle frequencies, but in jet-engined aeroplanes, the high sonic frequencies predominate. The peak frequency of a jet engine is about 2000 cycles per second, and the intensity of its noise is about 145 decibels. Exposure to such an intense sound will cause a considerable hearing loss for higher tones, and extremely severe tinnitus; but the frequencies of ultra-sound have little or no effect on hearing—it is the intensity rather than the frequency of a sound that produces damage.

There is very little evidence from pathological changes in man on the effects of intense sound and ultra-sound, but in guineapigs degenerative changes have been noted in the cochlea; the greater the intensity of sound, the greater are these changes. Once the ear has been damaged by noise, its susceptibility to further damage is increased.

Noise as an industrial hazard has not received enough attention. Attempts should be made to protect the ears—for example, by wearing ear plugs or helmets. The President thought that any worker who was to be exposed continuously to a noise of more than 90 decibels' intensity should have his hearing tested by modern audiometric methods before starting work and at intervals afterwards. Only in this way could employers determine the susceptibility of individual workers to noise. Another possible improvement was insulation of machinery against noise.

There were no grounds for supposing that ultrasonic frequencies caused disturbances of vestibular function.

In the subsequent discussion Mr. J. F. SIMPSON cited the case of a business man who had become deafened in the left ear from use of the telephone. He began to use his right ear, but this too became deaf. Did we know, he asked, any of the factors responsible for the very wide individual variation in susceptibility to noise? In reply, the PRESIDENT said that he already had a programme in view to study this problem. He felt that some idea of susceptibility could be gained from knowing the rate at which hearing recovered after exposure.

Reviews of Books

Diabetes and Pregnancy

Blood Sugar of Newborn Infants during Fasting and Glucose Administration. JORGEN PEDERSEN, Blegdamshospitalet, Copenhagen. Copenhagen: Danish Science Press. 1952. Pp. 230.

Dr. Pedersen here presents both his own work and its general background; and the extent of the survey as well as his own contributions make it of real value to researchers in this field.

He has measured the blood-sugar four times daily of some 20 diabetic women for 32 to 80 days before delivery, and computed the average pregnancy blood-sugar level. This, he finds, is inversely related to the average blood-sugar level of the infant during the first 24 hours of its existence (the "24-hour level"), whereas the blood-sugar of the mother half an hour before delivery is directly related to the infant's "24-hour level." Furthermore infants of diabetics had a lower 24-hour blood-sugar level than infants of normal mothers, even where there was no difference in the maternal blood-sugar levels at delivery. Infants of diabetics also differed from those of non-diabetics in that their first 24-hour blood-sugar level varied inversely with their birth weight.

Unlike the Chicago school, he does not recommend feeding glucose to the infants of diabetics in the first 24 hours, since he found that the blood-sugar did not fall progressively in spite of fasting, and he is sceptical of explaining their increased neonatal mortality on a basis of hypoglycæmia. He states however that he still considers the hyperinsulinism theory for the infants of diabetics "plausible."

Although this work is in many ways a model of a full, if rather verbose, presentation of data, it is marred by a number of typographical errors.

Cellular Changes with Age

WARREN ANDREW, PH.D., M.D., professor of anatomy, George Washington School of Medicine, Washington, D.C. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 74. 18*s.*

THE level of this useful review of recent work on the histobiology of ageing is that of the monographs contributed to Cowdry's celebrated textbook. It touches on some of the recent studies in the ultramicroscopic structure of collagen fibres, the comparative anatomy of neurone degeneration, and the pointers—more numerous than the known facts about ageing processes—towards useful lines of research.

Hemifacial Spasm

A Clinical and Pathophysiological Study. ROBERT WARTENBERG, M.D. London: Oxford University Press. 1952. Pp. 86. 32*s.*

THIS clinical monograph on an obscure phenomenon is in many ways a model of its kind. Dr. Wartenberg has taken a tiny problem, analysed it with precision, illustrated it by lucid case-notes and excellent photographs, and submitted an explanatory hypothesis with modesty, clarity, and balance.

He sets out clearly the neurological relation between hemifacial spasm of unknown origin and spasm following facial paralysis, and he believes that they should both be regarded as release phenomena. The causes of this release are still obscure, and perhaps he overstates his case when he suggests that infection by the mouth is the likeliest cause both of spasm and of paralysis of the facial nerve. However, he admits that this cannot at present be considered proven or even susceptible of proof; but as he shrewdly affirms, "A fertile error is of more value than a sterile fact."

The only criticism that may arise is the brevity of the section on therapy. Neurologists are apt to be more preoccupied with diagnosis than treatment, and Dr. Wartenberg is a trifle summary with surgical methods. For instance, the recent work of Marino and Alurralde, who practise peripheral selective neurotomy, perhaps deserves mention.

Culdoscopy

A New Technic in Gynecologic and Obstetric Diagnosis. ALBERT A. DECKER, M.D., F.A.C.S. Philadelphia and London: W. B. Saunders. 1952. Pp. 142. 17*s.* 6*d.*

THIS is a procedure which is gaining in popularity in the United States, and the time is ripe for a detailed description of its technique, scope, limitations, and risks. Only as regards the risks is Dr. Decker's book not quite satisfactory. A method that will often obviate laparotomy has obvious advantages, and many may be tempted to embark upon it because Dr. Decker emphasises the absence of complications and disasters. But in less practised hands unsuitable cases may be selected and accidents may well occur. He should perhaps have tempered his enthusiasm with warnings. Where bowel is adherent to the base of the pouch of Douglas—as a result of pelvic tuberculosis or endometriosis, for example—there is a real risk of injury, and only a high degree of clinical common sense and consistent luck will prevent such damage. In excluding tubal pregnancy the method is probably more valuable than for any other purpose. But there is always the danger that the general adoption of any new diagnostic or therapeutic measure will lead to abuses, and patients are hardly likely to find the experience a comfortable one, especially as the knee-chest position is essential.

The Medical Annual 1952 (Bristol: John Wright & Sons. London: Simpkin Marshall. 1952. Pp. 476. 27*s.* 6*d.*).—A year's medical news, distilled and condensed, makes strong drink: the annual is a little too potent perhaps for the student, who must risk a headache by sampling all the well-known vintages, but it is just the thing for those who need no longer keep so large a cellar. The editors, Sir Henry Tidy and Prof. A. Rendle Short, have again called for clear summaries of the more important publications of 1951, and their contributors have produced them by the score. The "literature," already unmanageable enough for most readers, gets more and more out of hand, and the annual has for many years been an excellent means of keeping it under control.

Spanish-English Chemical and Medical Dictionary (New York, Toronto, and London: McGraw-Hill Book Company. 1952. Pp. 610. £7 9*s.*).—The English-Spanish companion volume (reviewed in these columns on *Feb. 14*, 1948) has 692 pages and cost 50*s.*, its American price being $12. The volume now under review, compiled by the late Mr. Morris Goldberg, costs $17.50 in America, to which its English price of 149*s.* seems out of all proportion. Nor is it so superlatively good as to justify this enormous price; for, though it seems to include nearly all the words which, derived from Greek or from Latin, are almost the same in both English and Spanish, it omits many medical words of more Spanish character which could have been usefully included.

Textbook of Histology (6th ed. *Philadelphia and* London: W. B. Saunders. 1952. Pp. 616. 50*s.*).—Should anyone offer a prize for the best-illustrated textbook, "Maximow and Bloom" would be up there among the contenders—and the pictures of a pulmonary lobule and a section of the human pancreas would surely get a special mention. The book was originally planned in 1926 by the late Prof. A. A. Maximow, and the work was carried on after his death in 1928 by Prof. William Bloom, who has now directed another edition. Large parts of the book have been rewritten and many of the illustrations are new; an introductory chapter has been added which "correlates the submicroscopic, biochemical, and enzymatic constitution of cells with their structure and function" as seen through the optical microscope; and new accounts of the endocrine glands have been included.

THE LANCET

LONDON: SATURDAY, NOV. 15, 1952

Reversibility of Hypertension

The reversibility of hypertension is in no doubt when the causative disease is self-limited or can be cured. Thus in acute nephritis and toxæmia of pregnancy the blood-pressure returns to normal with resolution of the primary disease; removal of an adrenal tumour or a diseased kidney may likewise be followed by return of the blood-pressure to normal; and hypertension occurring in young adults during periods of stress may subside spontaneously. The real problem turns around the reversibility of chronic high blood-pressure. The change from a labile to a fixed level is a common sequence in both renal and essential hypertension, and in many cases fixation is followed by a progressive rise in pressure which may lead to a malignant termination, characterised by papillœdema and progressive renal failure. The mechanisms of fixation of the blood-pressure and of the transition from the benign to the malignant phase are unknown, as indeed are the mechanisms by which both renal and essential hypertension originate; and until these processes are understood it seems improbable that any reliable treatment of hypertension will be devised. Nevertheless certain facts have been established by clinical observation and animal experiment which must be taken into account both in the selection of cases for treatment and in the interpretation of results.

In the first place it is still of vital importance to make the distinction between essential hypertension and that due to primary renal disease. This distinction has been obscured in the past, and still is in some quarters, by two misconceptions—the first that essential hypertension is due to renal arteriosclerosis, and the second that the condition we now recognise as the malignant form of essential hypertension is a manifestation of chronic nephritis. Both these concepts found a place in the classification of Bright's disease by Volhard and Fahr,[1] who attributed hypertension in nephrosclerosis to degenerative lesions of the renal arteries and described malignant nephrosclerosis as a combination of the benign form and nephritis. Kimmelstiel and Wilson[2] first clearly showed that nephrosclerosis was a progressive development during the course of both benign and malignant hypertension and that, in the latter, renal lesions were slight in the early stages. These observations were strikingly confirmed when Wilson and Byrom[3] demonstrated by experiment on animals that hypertension could produce arterial and parenchymatous lesions in the kidney closely resembling those of malignant hypertension. This work presented an admirable opportunity to dispense with the two misconceptions which had previously obscured the relationship of essential hypertension with the kidney. Unfortunately, however, Goldblatt[4] dismissed the lesions described by Wilson and Byrom as artefacts and persisted in the view that his experiments provided unequivocal evidence on the one hand that essential hypertension is due to renal arteriosclerosis and on the other that uræmia is an essential factor in producing the lesions of malignant hypertension. Byrom and Dodson[5] refuted this argument when they produced arteriolar necroses in the rat kidney after forcibly raising renal blood-pressure by intra-arterial saline injection. Wilson and Byrom justifiably concluded that malignant hypertension, with its histological counterpart malignant nephrosclerosis, was a syndrome which might complicate any form of hypertensive disease. The value of these experimental studies in the interpretation of the natural history of various forms of hypertensive Bright's disease was emphasised by Ellis in his Croonian lectures.[6]

It is now common experience that papillœdema, the diagnostic sign of malignant hypertension, usually subsides if the blood-pressure can be reduced by sympathectomy or hexamethonium drugs, and this is true whether the underlying disorder is essential hypertension or primary renal disease. Elsewhere in this issue Professor Pickering and his colleagues describe such a reversal of papillœdema in three cases of pyelonephritis severally treated by nephrectomy, subtotal adrenalectomy, or sympathectomy. In all three, acute vascular necroses were found in the adrenals and in sections of kidney removed at operation, but the writers had no opportunity to observe the reversal of these lesions. They present the thesis that therapeutic reduction of blood-pressure can change malignant hypertension to benign and that the benign and malignant courses are merely expressive of the severity of the hypertensive process irrespective of the underlying lesion. While this thesis is broadly acceptable there is nevertheless considerable evidence that the level of high blood-pressure cannot alone account for the malignant change. Women may sustain for half a lifetime a degree of hypertension which in men would almost certainly change to the malignant form in a few years. Similar qualitative differences in response to high blood-pressures have been observed in animals. It seems likely that there is some individual susceptibility of the arteries and arterioles which produces an exaggerated vasoconstrictor response to rise in intra-arterial tension. The reversibility or otherwise of the process may then well be determined by the resulting damage to the renal vessels. Pickering and his colleagues regard the successful reduction of blood-pressure in their three cases as evidence against the concept of a vicious circle (put forward by Wilson and Byrom[7]) in which hypertensive renal vascular lesions perpetuate and aggravate the hypertension. They agree that alternatively a vicious circle may exist which apparently can be broken in the early stages. One cannot overlook the fact that many cases of unilateral renal disease continue with sustained hypertension after nephrectomy, and the clinical features of the malignant phase may return after an apparent reversal. In essential hypertension, moreover, a change from the malignant to the benign type for more than a few years is uncommon and even so the blood-pressure usually

remains at a high level; in benign hypertension, on the other hand, restoration of blood-pressure to normal by sympathectomy is often successful. It is hard to avoid the conclusion that the comparative irreversibility of malignant hypertension, whether essential or renal, is due to secondary renal vascular lesions—i.e., arterial necrosis and endarteritis which produce irreversible renal ischæmia.

The experiments of BYROM and DODSON[8] and FLOYER[9] have confirmed WILSON and BYROM's conclusion that persistent hypertension after removal of the ischæmic kidney is attributable to secondary changes in the opposite kidney. That similar lesions occur in the opposite kidney in patients with hypertension due to unilateral renal disease is now well recognised.[10] It is possibly hazardous therefore to claim reversibility of malignant hypertension without full reference to the underlying cause of the hypertension and the possible influence of secondary renal lesions. Much confusion still derives from the use of "malignant hypertension" as a diagnostic label in primary renal disease. In view of the terminological obscurantism which Bright's disease produces in most of its devotees it would be better to speak (though not in the hearing of the patient) of benign and malignant essential hypertension, and in primary renal disease to follow the time-honoured tradition of choosing a name which indicates the primary disorder rather than a late and still somewhat uncertain complication.

Preventing Poliomyelitis

EXCITING news of poliomyelitis was given at the annual meeting of the American Public Health Association.[11] Dr. W. McD. HAMMON described the results which he and his colleagues have had in a carefully conducted trial of the protective effect of gamma-globulin in poliomyelitis.[12] Extensive field tests were made during poliomyelitis epidemics in Utah, Texas, Iowa, and Nebraska in 1951 and 1952. Of nearly 55,000 children, aged from one to eleven years, half received an intramuscular injection of gamma-globulin, while the remainder were injected with gelatin solution. The solutions looked exactly alike and strict precautions were taken to ensure that until all assessments had been made no-one concerned with the trial knew which children received the gamma-globulin. There were 64 cases of paralytic poliomyelitis among the control children, compared with 26 among those receiving gamma-globulin. In the first week following the injection of gamma-globulin the degree of protection was barely significant, but HAMMON et al. think that in the late stages of the incubation period gamma-globulin may modify the severity of the paralysis without preventing it altogether. During the second week the degree of protection increased greatly, for only 3 children who had had gamma-globulin got poliomyelitis, compared with 23 who had had gelatin. This increased protection was maintained until the end of the fifth week; thus, between the second and fifth weeks 6 cases occurred in the gamma-globulin group and 38 in the controls. True, protection was short-lived, in spite of the fact that large amounts of gamma-globulin were given: on the basis of body-weight, an average five-year-old child received 7 ml. Nevertheless, this is the first prophylactic measure which has significantly reduced the incidence of paralytic poliomyelitis. STOKES et al.[13] have suggested that gamma-globulin, given to children who have been exposed to the virus of *infective hepatitis*, may, instead of preventing the disease, modify it in such a way that a subclinical infection with lasting immunity results. It may be that a similar effect in this poliomyelitis trial will prolong the period of protection in certain individuals; alternatively gamma-globulin may prevent subclinical infections, so that its action would be less favourable in the long run; but it is too early to assess these possibilities. Of course, gamma-globulin has been used before in attempts to protect children exposed to poliomyelitis; but this is the first evidence to suggest that poliomyelitis may take its place beside measles and infective hepatitis as a disease in which those at risk can be protected in this way.

At the same meeting,[14] Dr. H. A. HOWE described the use of an inactivated poliomyelitis vaccine in children. It has been well established that monkeys can be protected against large doses of poliomyelitis virus by intramuscular injections of an inactive vaccine, and HOWE's experiments are the clinical application of these findings. The vaccine was prepared from the brain of an infected monkey, and the brain was treated with formaldehyde to inactivate the virus. Strains of all three serological types of poliomyelitis virus were incorporated in the vaccine, for injection with one strain gives little protection against heterologous types. These polyvalent vaccines produced no untoward reactions in 6 children to whom they were given, and significant levels of antibody to the three serological types of virus developed in the children's sera. Serum antibody is known to be effective against experimental poliomyelitis, and there is also evidence that after invading the gastro-intestinal tract the virus reaches the nervous system by way of the blood-stream[15]; it is therefore reasonable to suggest that these children may be protected against paralytic poliomyelitis. HOWE pointed out, however, that the vaccine might still require many modifications in order to increase its effectiveness and abolish the risk of allergic encephalomyelitis.

These are clearly important steps towards the prevention of poliomyelitis, but it is probably best to regard them, for the time being only, as pointers to further research. To protect a large number of people in this way gamma-globulin would be required in such enormous amounts that we may be faced with the possibility of exsanguinating half the population to protect the rest. The use of inactivated vaccines on a large scale may raise a similar problem, for one monkey might be needed to provide enough virus to vaccinate a single child successfully. The only clear way out of this impasse is to use live attenuated virus vaccines; here two difficulties arise—the preparation of attenuated strains of poliomyelitis virus and their testing in human beings—

and some progress has already been made towards overcoming them. The successful cultivation of poliomyelitis viruses in tissue cultures by Enders and his colleagues,[16] and the subsequent confirmation and extension of this work in many American laboratories, has given a strong stimulus to the search for attenuated variants. Underlying much of this work is the belief that the poliomyelitis viruses are not strictly neurotropic; and here Scherer and Syverton[17] have lately shown that poliomyelitis viruses can multiply in microscopically "pure" cultures of fibroblasts in vitro. Arguing on the analogy of other virus diseases, it may be possible to select in this way variants of poliomyelitis virus which have a low virulence for nerve-cells. Another report[18] from the United States says that Dr. H. R. Cox has grown the Lansing strain of virus in the chick embryo; and if the method can be extended to other strains, this may help to provide enough tissue to grow the virus cheaply and abundantly. The second problem, that of testing the vaccine in human beings, has already been tackled by Koprowski et al.,[19] who fed 20 volunteers with an attenuated variant of the Lansing strain without mishap. The risks of this sort of experiment are considerable, but it can reasonably be argued that urgent methods are justified. Many technical difficulties have yet to be overcome, but the progress of poliomyelitis research during the past ten years gives us good reason to hope that success, if not yet in sight, will surely come.

Tubercle Bacilli in the Tissues

There is still much to be learnt about the behaviour of tubercle bacilli in the tissues. Why, for instance, are the bacilli so scarce in the centre of caseous masses and so abundant in the cavities formed by their excavation? It has been suggested that in caseous material low oxygen tension and organic acids do not favour bacterial multiplication. Sometimes the bacilli are so altered that, although they have the usual morphology and staining properties in direct smears, they fail to grow on culture-media and do not cause disease in animals.[20–22] Such bacilli may be dead; on the other hand they may have lost only temporarily the ability to reproduce, and alteration of the environment may restore them to normal activity. The fate of tubercle bacilli in the tissues does not seem to depend simply on the recognised immune processes. Certain extracts of animal tissue are now known to retard the growth of tubercle bacilli in vitro. Hirsch and Dubos[23] have isolated from these extracts a crystalline inhibitory substance, spermine. This is present in many animal tissues, and especially the prostate and pancreas; and in cases of pneumonia, tuberculosis, and cancer the diseased tissue consistently contains more spermine than a normal portion of the same organ. The tuberculostatic action of spermine can only be demonstrated in vitro when a certain fraction of bovine serum-albumin is present. Its action in the body may, therefore, depend on the environment provided by a particular tissue. An inhibitory substance has also been found in extracts of tuberculous lymph-nodes[24]; this has not been isolated or identified, and its relation to spermine is unknown, but extracts of healthy lymph-nodes do not have an inhibitory action.

Knowledge of the behaviour of tubercle bacilli in the tissues has been extended by direct observation of the bacilli within living cells. Mackaness[25] in this country and Suter[26] in the U.S.A. have investigated the interaction of tubercle bacilli and macrophages in tissue culture. The bacilli were readily ingested by the macrophages, and if enough bacilli were present the cells disintegrated. The bacilli could also multiply within the cells and eventually kill them. Mackaness investigated the action of several substances on this intracellular growth. Streptomycin inhibited such growth only when its concentration in the culture-medium was many times that required to inhibit extracellular growth of the same strain. *p*-Aminosalicylic acid (P.A.S.) had hardly any effect even in high concentrations, but isoniazid was equally active against intracellular bacilli and those grown in a liquid medium.[27, 28] With fully bacteriostatic concentrations of both streptomycin and isoniazid the intracellular bacilli remained viable for at least seven days. Even double this concentration of streptomycin (a level most unlikely to be reached in the body) did not kill all the bacilli. The bactericidal activity of isoniazid in high concentrations has yet to be investigated.

The effect on tubercle bacilli of a substance in an artificial culture-medium can give only a hint of what happens in the body. To speak of an effective serum-concentration of an antibacterial agent is meaningless, unless clinical trials have shown that a response is obtained only when such a concentration is reached. The inhibitory concentration observed in the laboratory may vary with the strain of bacillus, the composition of the culture-medium, the size of the inoculum, and the period of incubation; and to these factors must now be added the intracellular or extracellular position of the bacilli. It is not possible to reproduce exactly the condition within each type of tuberculous lesion; and even if this were possible, it would also be necessary to estimate the concentration of the antibacterial agent within the lesions during treatment, and to relate this to the concentration in the blood-stream, before deducing the clinical effect of particular serum-levels and schemes of dosage. Streptomycin was first used in doses of 0·5 g. every six hours, to maintain a constant high level in the blood. It was then found that 1 g. daily was no less effective, and that this could be given in a single dose. Now it is claimed that 1 g. can be administered twice weekly together with P.A.S. daily without much, if any, loss of therapeutic effect. The observations of the physician are not easily reconciled with the findings of the bacteriologist; but then the tubercle bacillus behaves very differently in the test-tube and in the tissues.

Annotations

THE UNWILLING PATIENT

THE Royal Medico-Psychological Association's Maudsley lecture for this year was given on Nov. 6 by Dr. W. Rees Thomas, senior medical commissioner of the Board of Control, who spoke about the changing public attitude towards the incarceration of the insane, and in particular about the progress of British legislation on insanity since the 18th century. From ancient times, he said, the popular idea of the insane equated lunacy with violence. The madman was often believed to be possessed by spirits or to have exchanged his soul for that of another, and his treatment might consist in a religious ceremony or in close confinement and neglect —" the dark house and the whip " of Shakespeare, and very often the restraint of chains. This was quite consistent with a belief in love towards all men, for the lunatic was thought to have lost his humanity. It was above all the French physician Pinel who led the way to the modern view. Writing in 1806, for instance, he denied that it was necessary or advantageous to bind or chain the insane. Control could be achieved by producing a balance between their passions, and the ideal psychiatrist was he who concealed from the patient any restraint he might have to use.

The incidence of mental disorder in the past was difficult to compute, though after 1840 note was kept of the number of patients shut up. Continental writers in the 18th century referred to attacks of the vapours, nerves, and distemper as the " English malady," and said that a third of the people of condition in England were affected—an estimate not unlike that for neurosis today. Two hundred years ago, however, mental illness got little official notice. An act of 1744 merely empowered any two justices of the peace to lock up and chain any poor man they judged insane, while the well-to-do could be imprisoned by relatives or friends without any check whatsoever. The improved handling of the unwilling patient since those days could be regarded as the development of external control over the conduct of mental homes and hospitals, and also as the amelioration of the conditions within them, particularly the abandoning of chaining. It was long thought that a period of restraint by chaining was necessary to induce the patient to submit to the authority of the physician, just as later there were some who claimed that the dark house was of therapeutic value. Under Dr. Charlesworth the hospital at Lincoln now called The Lawn was a pioneer in freeing the patients. In 1829 over half were under restraint : eight years later less than 2% were still so controlled. At first there was no segregation of the sexes, and no separate rooms for the excited ; patients sometimes came to blows and injured one another. This led to criticism of the new policy which was really criticism of the inadequacy of the old building. But public feeling was changing. Advertisements of licensed private mental homes in the 1840s promised " no restraint," though they sometimes used it on the quiet. Lord Shaftesbury, who was chairman of the Commissioners in Lunacy for forty years from 1845, was very active in promoting the new humanity in all the hospitals within his jurisdiction. Colney Hatch, in particular, seems to have given trouble, the medical staff claiming that chaining and other forms of physical restraint were less disagreeable to the insane than to normal people, that they were better than surveillance by a bad attendant, and that they were more economical of staff and bedding. In 1866, when it was found that the same hospital was shutting up patients naked, with only bare boards to lie on day and night for weeks on end, the plea was that this was the patients' own choice.

Gradually buildings were improved, and more money provided for attendants, who were better selected and trained. Records came to be kept of what each patient did each day, and seclusion, instead of being ordered on the authority of the nurse, was reserved to the doctor and used only for purposes of treatment. Finally today's regulations were established by the Lunacy Act of 1890.

In the 18th century a man could rid himself of an inconvenient wife, or a relative who stood between him and a fortune, by placing them in a private mental home. This imprisonment of the sane caused many scandals and led in 1744 to the licensing of all such houses by a commission of five physicians in the Metropolitan area and by magistrates elsewhere. Such homes had to be inspected at least once a year. The act of 1828 enlarged the commission by the addition of ten laymen, and insisted that each licensed house caring for more than 120 patients must have a resident physician. It also for the first time made a doctor's certificate necessary before the insane poor (but not the well-to-do) could be committed to an asylum, though it was not till 1853 that the diagnosis of unsound mind had to be supported by facts. Another step forward came in 1842 when the Metropolitan commission was given power over the whole of England and Wales in place of the justices. Although a mid-19th-century Lord Chief Justice had expressed the view that patients should only be confined if they endangered themselves or others, the way in which opinion was moving was shown by an incident in 1862 when a Member of Parliament who was a patient in a private mental home was allowed out from 8 P.M. to 2 A.M. to record his vote in the House. The doctor responsible for this permission was forced to resign. Finally in 1877 a Select Committee of the House of Commons considered what should be the relation of law on lunacy to the laws guaranteeing individual liberty, and the present regulations governing certification were codified in the Act of 1890.

Voluntary patients were first heard of after 1854, when licensed houses were allowed to keep patients after discharge if they wished to stay, and also to take relatives and friends as boarders. In each individual case, however, permission had to be given by two commissioners, who might call at any time to see the person in question. Later, anyone who had been a mental patient some time in the preceding five years was also made eligible for voluntary admission in this way. It was not till as recently as 1930 that voluntary patients were at last admitted to hospital without the central authority's consent in each instance. Today the extent of voluntary admissions varies from hospital to hospital, being anything from 45 to 94% of the total admissions in different parts of the country. Dr. Rees Thomas looked forward to the time when admissions for mental illness will be regarded no differently from those for other causes. He hoped also that temporary detention will be extended to those patients who are opposed to admission only by reason of their illness, so that certification will fall altogether into disuse.

DENTAL TREATMENT OF CHILDREN

LETTERS in our last issue suggest that the only factor preventing a large increase in the number of qualified dentists is the lack of facilities for training them, and that the introduction of dental ancillaries would further impede expansion of the profession, because the ancillaries would occupy places in the dental schools which might be filled by dental students. Our correspondents contend that, were it only possible to enlarge existing schools and found new training establishments, there would be, or could be, enough suitable applicants for admission as dental students to the dental schools to permit a rapid expansion of the profession to a size commensurate with its responsibilities. We, on the other hand, believe that this view is quite unrealistic and that the number of suitable candidates is limited. At the present moment, of the students who satisfy the scholastic and other conditions of entry to the schools, far too many fail to complete their training at all or take longer to qualify than the prescribed number of years of study, because they are unable to pass one or more of their qualifying examinations. The result is a considerable waste of training facilities, which would become even greater were the intake into the schools to be increased threefold, as the Teviot Committee estimated would be essential in order to double the size of the dental profession over the next twenty years. At present, we understand, no candidate with the necessary entrance qualifications is unable to find a place as a dental student in one or other of the schools. If that is so, trebling of the annual intake would almost certainly entail lowering of the conditions of entry, in order to admit into the schools a large number of students who would be considered unsuitable by present criteria. As a corollary, to enable these additional students to complete their course of study, it would be necessary to lower the standards of training and of the qualifying examinations. We are quite sure that most dentists would reject the idea that, in future, students should enter the profession after a training inferior to that now demanded by the licensing bodies. The price of lowered standards of training would be too great to pay, especially as the efficiency of the profession at its present size could be greatly raised if it were supplemented by ancillaries specially trained to relieve the dental surgeon of many of the simple routine tasks of children's dentistry.

In New Zealand, the training establishment for dental nurses is separate from and independent of the dental school, and there is thus no question of dental nurse trainees occupying places which might otherwise have been filled by dental students. The school dental nurses scheme is far from having had a deleterious effect on the general dental service to the community, for there are in New Zealand twice as many dentists in proportion to the size of population as there are over here. In that country, professional and public opinion share a confidence in the scheme and a belief that it must continue in being.

The fear expressed that the Dentists Bill did not provide for sufficiently close supervision of the work of the dental ancillaries appears exaggerated. The Bill proposed no more than a three-year experiment in training and employing ancillaries, under the direction of the General Dental Council. This body, which was also to be set up when the Bill's proposals became law, would consist of 40 members, of whom at least 30 would be dentists, and only 4 of the 7 Crown nominees would be laymen. According to the relevant clauses of the Bill, it was this council that was to frame the regulations governing the experiment and would ensure " that dental work . . . is carried out by an ancillary dental worker only under the supervision of a registered dentist." It is inconceivable that a body so overwhelmingly composed of dentists and doctors should not be able to ensure close personal supervision by dentists of the work of the ancillaries during the period of the experiment. Moreover, the General Dental Council was to be the judge of the success of the experiment and to advise the Government whether the employment of ancillaries had been justified or should be abandoned. Neither the public interest nor that of the dental profession could have more complete safeguards than these.

When Dr. MacGregor uses the phrase " panic legislation," we can only wonder whether he is talking about the same Bill. This issue has now been debated for many years, during which the lack of proper care for children's teeth has been a blot on our health services. In the long run, the only practicable way of providing that care is to enlarge the dental schools, or build new ones, so as to produce more dental surgeons (if suitable candidates are available) or to produce ancillaries. If the course for ancillaries were half as long as the course for dental surgeons, a given school could presumably produce ancillaries a great deal faster than it could produce dentists. Naturally training in a new school (whether for dentists or ancillaries) would be far more expensive than training in an old one, built and equipped when things were cheaper; but if training for ancillaries lasted half as long as training for dentists, it is hard to see why, in a given school, it should cost much more than half as much per head. Let us at any rate try the experiment.

A NEW ANTISEPTIC

A REPORT[1] from a large maternity hospital in France describes the successful results obtained with a saponium, one of the quaternary ammonium compounds, which was used in place of all other chemical disinfectants in the surgical and obstetric routine of the hospital. The antiseptic (methyl-phenyl-dodecyl-trimethyl ammonium methosulphate) was used for the hands of the attendants, for the skin and vaginal toilet of the patient, for finger-stalls, and for sterilisation of forceps and other instruments. Dilute solutions (0·4–0·5%) in warm, not hot, water were used, and it was important to avoid the presence of the ordinary anionic soaps which inactivate these cationic agents. Other advantages claimed for this new antiseptic are its low cost, its small bulk for transport, and its value in disinfecting the many light plastic pieces of apparatus that do not stand heat sterilisation. These properties suggest that this antiseptic would be valuable when large numbers of people are being immunised or treated by injection, particularly in places with few facilities for heat sterilisation. Instruments could be treated with the antiseptic after degreasing with ether—or a mixture of the antiseptic with water, alcohol, and amyl acetate could be used.

Although earlier work on this group of chemicals had been done in the United States, the great possibilities of these compounds as antiseptics were first noted in 1935 by Domagk,[2] who demonstrated germicidal properties in all quaternary ammonium salts in which at least one radical was a long-chain aliphatic group. These compounds are available under various official or trade names—e.g., cetrimide, 'Zephiran,' 'Phemerol,' 'Roccal,' and 'Bradosol.' Their properties have been reviewed by Rahn and Van Eseltine,[3] and by Berry.[4] They are surface-wetting agents and their bacteriostatic action is probably due to reversible interference with the mechanism of synthesis or cell division. Their mode of action as lethal agents is not certain; they may disrupt the bacterial cell membrane or inactivate enzymes or indispensable proteins. They are neutralised by soaps and by phospholipids, and, as they are adsorbed not only by bacteria but by precipitated proteins, they are less effective in vivo or in the presence of serum. They are most active in the alkaline range of pH, and they are ineffective in an acid environment. They are non-toxic to animals in the concentrations in which they are commonly applied. A wide range of bacterial species are susceptible to their action, but they have no appreciable effect on the pseudomonas group, the tubercle bacillus, or bacterial spores.

Assessment of the quaternary ammonium salts as bactericidal agents is fraught with certain technical difficulties. Tests for sterility are invalidated by the bacteriostatic action of small amounts of the agent carried over with the transferred bacteria, and specific antidotes must be used. The determination of phenol

coefficients is of little value, especially for purposes such as the sterilisation of surgical instruments, where absolute sterility, including the killing of spores, is demanded. For hospital purposes, and particularly for the disinfection of the skin before operation, good results have been obtained by a number of workers. Kramer and Sedwitz,[5] used 'Ceepryn' in about 18,000 cases and they had no infections or irritation of the skin. However, Miller and his colleagues[6] have given a warning that the peculiar orientation of the antiseptic molecule on the skin surface may result in the retention of living bacteria on the under layer of an invisible film formed on the skin. We have already mentioned[7] some other difficulties which arise when judging the merits of various methods of skin disinfection. The quaternary ammonium salts certainly offer great possibilities, but it would be a help to have more information about their activity and suitability for surgical practice.

NUTRITION IN INDIA

WIDESPREAD malnutrition among the peoples of India unhappily offers considerable opportunities for research into the metabolic disorders to which it gives rise. It is clear from the latest report[8] of the Nutrition Research Laboratories at Coonoor, South India, that the Indian Council of Medical Research are making full use of these opportunities, and they are encouraging both field studies and fundamental research. Among the work of the institute during the past year, that of greatest general interest deals with nutritional œdema in adults and children—probably the commonest nutritional disease in India. The condition in adults is considered separately from that in children; but the disease is fundamentally the same at all ages, and the cause is certainly the same—a severe deficiency of calories and protein in the diet. The brief but excellent account of the clinical picture given in the report shows the close resemblance to what is called kwashiorkor in Africa.

The cause of the œdema has received particular attention. The plasma-protein level was appreciably reduced in all cases in which it was measured; the main fall was in the albumin, and usually the globulin level was correspondingly raised. The incidence and severity of œdema, however, showed only a poor correlation with the plasma-protein values; perhaps closer correlation may exist between œdema and the osmotic pressure of the plasma proteins, but this point does not seem to have been investigated. The importance of increased capillary permeability is also discounted, for the protein content of the œdema fluid is extremely low. The œdema differs therefore from the ascites of hepatic cirrhosis, with which it seems at first sight to have much in common, because the protein content of ascitic fluid usually exceeds 3%. An interesting observation was the excretion in the urine of an antidiuretic substance, demonstrable in the concentrated non-dialysable fraction. The Indian workers are particularly impressed with this evidence of hormonal imbalance, and they attribute it, as others have done, to impaired hepatic function, which is now well known to be associated with hypolipotropic protein-deficient diets. Loss of libido and gynæcomastia in adult males provided further evidence of hormonal disturbances. The sequence of events leading from malnutrition to œdema is still far from clear, and it is rather doubtful whether the antidiuretic substance in the urine is of much importance. Little attention has been paid in the last few years to changes in the water-binding capacity of the connective tissue, yet it is a change of this kind that might well be brought about by both nutritional and hormonal influences. The effects of the adrenal cortical-hormones on connective-tissue ground-substance may well be of significance in this respect. Moreover, signs suggestive of hypothyroidism are present in many of these cases; definite bradycardia, "thick" speech, sparse hair, and subnormal temperature may lead to a mistaken diagnosis of myxœdema. The relatively low specific-gravity of the urine (1013–1018), despite pronounced oliguria of 200–400 ml. per day, also suggests a considerable reduction in catabolic activity.

A technique for distinguishing between the lipase and esterase activity of the plasma is also described in the report, and the results of their estimation in nutritional œdema are of some interest.[9] There is reason to believe that the plasma lipase is normally produced by the pancreas and the plasma esterase by the liver. A distinct fall in the plasma level of these enzymes therefore suggests pancreatic and hepatic damage respectively. A fall in the level of both these enzymes has been reported in nutritional œdema and this could be explained by the damage to the liver and pancreas which has been demonstrated in this disease.

PAPILLŒDEMA

THE papillœdema of raised intracranial pressure is usually easy to recognise but occasionally it may be difficult. Discussing this question, Chamlin and Davidoff[10] emphasise the importance of measuring the size of the blind-spot when the diagnosis of papillœdema is in doubt on the ophthalmoscopic appearance alone. The blind-spot should be plotted on a Bjerrum screen at a distance of 2 m.; and, with a white test object of 10 mm. diameter, its normal size is reasonably constant, the width being 5·5° and the length 7·5°. This absolute blind-spot is surrounded by a 1° pericæcal amblyopic zone, which is best plotted with a 2 mm. white test object; this zone corresponds to the area around the optic disc where the rods and cones are less sensitive than in other parts of the retina. The authors say that they have never seen papillœdema with a completely normal blind-spot and pericæcal amblyopic zone when its size is plotted with a 2 mm. test object. On the other hand, they have found enlargement of the blind-spot before there is ophthalmoscopic evidence of papillœdema.

Enlargement of the blind-spot may also be found with myopic degeneration around the disc, with medullated nerve-fibres, and with juxtapapillary choroiditis, but the ophthalmoscopic appearances of these conditions are not likely to be confused with papillœdema. The three conditions which are most likely to cause difficulty are pseudopapillœdema, hyaline bodies in the disc, and occasional cases of retrobulbar neuritis. Pseudopapillœdema is the name given to a congenital condition in which the optic discs may appear to be swollen and may actually be elevated several diopters, but in which there is no œdema and no disturbance of the retinal neuroepithelium. The condition is most often seen in association with hypermetropia, and it is of no serious pathological significance. No enlargement of the blind-spot is found in pseudopapillœdema,[11] and this fact is of considerable value in distinguishing it from true papillœdema—a distinction which may at times be difficult on the ophthalmoscopic appearances alone. Moreover, in pseudopapillœdema the appearances remain unchanged, in contrast to the usual sequel of events in true papillœdema. Hyaline bodies in the optic nerve-head are also a developmental abnormality in which whitish or yellowish tissue accumulates in front of the lamina cribrosa. This accumulation may push aside the rods

and cones, and thus cause enlargement of the blind-spot, so this point is not helpful in the differentiation from papillœdema. Retinal hæmorrhages do not occur with this abnormality. In many cases the hyaline tissue forms rounded refractile excrescences (*Drusen*), and if the edge of one of these can be distinguished the diagnosis can usually be made. If, however, they are buried beneath the surface of the disc, the appearance may be very similar to true papillœdema. In the absence of other symptoms or signs indicating the need for pneumo-encephalography or cerebral angiography, the best course is to examine the patient at regular intervals, for the appearance of hyaline bodies will remain unchanged.

In a few patients suffering from retrobulbar neuritis, gross swelling of the optic disc, congestion of the retinal veins, hæmorrhages, and exudate may be seen, and the diagnosis from papillœdema due to raised intracranial pressure by the ophthalmoscopic appearance alone may be impossible. The diagnosis is often made clear by the sudden onset of visual impairment in retrobulbar neuritis, and by the fact that usually one eye only is affected, but the changes in the visual field are the most important differential point. In retrobulbar neuritis the pathological process, usually disseminated sclerosis, involves the papillomacular bundle, resulting in a centrocæcal scotoma. Less commonly there is a paracentral scotoma or a nerve-fibre bundle defect—findings quite distinct from the enlargement of the blind-spot which is found with the papillœdema of raised intracranial pressure.

CONCEPTION CONTROL

There is still a good deal of prudery in our attitude to contraception. When the Medical Women's Federation in 1949 asked medical schools whether they gave their students any guidance on this subject[1] only 4 out of 27 said that they did; and such a defect in the training of general practitioners is really indefensible, unless on religious grounds. In a valuable lecture[2] Mr. N. W. Pirie, F.R.S., points out that, for successful use, the present contraceptive methods often require skill and intelligence, and that many of the 50,000 or more illegal abortions believed to be performed every year in this country must be the sequel to a contraceptive failure. Yet little research is going forward to find better methods, although bull semen from artificial-insemination centres and human semen from subfertility clinics is often available for experiment. Part of the reason, he thinks, must be a taboo on the study of this kind of physiology; otherwise pharmaceutical manufacturers would routinely test their new antibacterial products on spermatozoa "just in case," and biochemists would study the metabolism of the gametes with the enthusiasm they have devoted to yeast and muscle.

To get away from the limited aim of finding more effective spermicides and better diaphragms, Pirie wants the problem viewed against a background of more fundamental research on sexual function—a change which is marked by talking no longer of "contraception" but of "conception control." Each stage in the production, maturation, and union of ovum and sperm can be analysed to see what the chances are of preventing it. Perhaps the cervical mucus can be rendered impenetrable to motile sperm; perhaps the maturation of the ovum in its follicle can be delayed; perhaps the union of the gametes in the fallopian tube can be prevented—as seems to have been achieved in the rat by inhibiting its sperm hyaluronidase with phosphorylated hesperidin.[3] Implantation of the fertilised ovum could probably be stopped by something much less drastic than a Grafenberg ring in the uterus, and the possibility is worth investigation with the aid of all the new biochemical knowledge of the last twenty years. The factors controlling fertility, fertilisation, and viability are of general biological interest in their own right. Knowledge of them is likely to be valuable clinically in treating involuntary sterility. If in addition contraception can be simplified and perfected, the majority of laymen will be thankful. The case for more research is unassailable, and it is to be hoped that Pirie's original appeal[4] for it has not fallen on deaf ears.

But how far a new simple contraceptive will help to avert the threat of world overpopulation is another matter. It is not merely that the most warlike nations are the least interested in limiting births, or that the giving of contraceptive advice to backward peoples is fraught with political difficulties, as a debate at the last World Health Assembly showed. Many of these backward peoples already practise contraception of a kind—e.g., with intravaginal bark pads in some parts of Africa, and oral plant extracts in the Pacific[5]—but the practice has a prescribed place in their culture and may only be used on certain defined occasions—for instance, before marriage. It must be recognised that in some societies to have few children is to court social ostracism or to be enfeebled economically.[6] These social and psychological factors cannot be ignored or disregarded, and very much more study of them will be needed before Western European ideas can replace the tribal taboos.

One other kind of conception control is also possible. It removes all responsibility from the individual and gives it to the government. This is the possibility of diminishing fertility by means of substances added to the national diet—for instance, mixing some long-acting contraceptive in the national loaf. So far, perhaps fortunately, such a substance is not known, and the large funds probably needed for the successful prosecution of such research are not forthcoming. But they no doubt would be if someone saw that reduction of an opponent's fertility was a practicable method of biological warfare. The prospect of man's complete control over reproductive processes, which science promises him, is a frightening one indeed.

ELECTRON MICROSCOPY AND SMALLPOX

The electron microscope has been directed on viruses mainly as a research tool. However, in confirmation of an earlier paper,[7] Lépine and Croissant[8] now suggest that it may be of assistance in the laboratory diagnosis of smallpox. One or two drops of blood-free fluid from fresh vesicles are suspended in distilled water, the mixture is allowed to settle in a fine tube, and the supernatant liquid is then dried and shadowed. The authors claim that, by examining electron micrographs of material prepared in this way, it is possible to differentiate smallpox from chickenpox. The elementary bodies of smallpox and vaccinia are on the average slightly larger and more rectangular than those of chickenpox. However, the largest of the chickenpox elementary bodies are much the same size as the smallest of the vaccinia and smallpox ones, so that a careful statistical evaluation would be required before size could be accepted as a reliable differential feature in any given case. Rake et al.[9] described the elementary bodies of chickenpox as brick-shaped, but Lépine and Croissant do not agree; differences in technique or in the material examined may account for these discrepancies. However, it is difficult to see the point of the new technique, when there are much simpler

and more reliable methods, such as those advocated by Downie,[10] for the differential diagnosis of smallpox. Downie claimed that direct microscopic examination of vesicle fluid and direct complement-fixation tests of crusts often give a quick and reliable answer, and that egg culture will bring early confirmation. These are well-tried diagnostic methods which appeal as much to the public-health authorities as to the laboratory worker. On the other hand, if electron microscopy could be combined with serological techniques—e.g., in a direct serum-agglutination test—it would add greatly to the precision of such methods.

THE END OF AN INSTITUTE

THE Oxford Institute of Social Medicine, as conceived by John Ryle, its first director, had not reached maturity when he died; and it will disappoint many who shared his belief in its potentialities that it is now to be brought to an end—anyhow in its present form; for the final report, prepared by his successor Dr. Alice Stewart, describes many promising projects which are still incomplete. But at all events the institute has gathered experience which will be valuable to others, and particularly, as Sir Ernest Rock Carling, chairman of the institute's committee, points out in a foreword, has established the value of the "combined" no less than the self-contained survey. The combined survey takes advantage of material already accessible, or anyhow easy of access. There are many competent people—clinicians, health visitors, overseers in factories, Government officials, and others—working in jobs which enable them to collect data of importance to social medicine; and, given straightforward instructions, they willingly coöperate.

Examples of such combined surveys mentioned in the report include studies of tuberculosis in Northamptonshire, begun in the boot-and-shoe industry, and later extended to other populations. The findings strengthen the view that infection at work is an important factor in the tuberculosis morbidity of adults, and that the chronic active case is the chief source of danger to workers in light industries. Studies, in two factories, of absenteeism from all causes showed that voluntary absences were positively correlated with the numbers in the working group; which reinforces the common belief that morale is better in small than in large working units. An influenza study showed that, as far as transmission of this disease goes, every worker is "in effective contact" with every other regular occupant of his workshop, no matter how the machines or benches are arranged. In 1947, the Royal College of Physicians initiated a survey of the social factors in the incidence and course of acute rheumatism in children, and in 1951 it sent the institute records collected in various parts of the country during three and a half years. Analyses of these records show that in the areas selected there was more disease in towns than in the country, and more among the children of working-class people than among the children of professional and administrative workers. Opportunity for infection, however, appears to be the important factor determining incidence, and there was no evidence that disease was directly associated with either bad housing or poverty. The incidence in blue-eyed children was 50% below expectation; and in children who had had tonsillitis the risk of developing rheumatism was thought to be considerably reduced if the tonsils were removed—a conclusion which has been criticised in our correspondence columns.[11] Another copious source of information has been tapped in the records of the civilian medical boards. From a sample of 23,322 men between the ages of 17 and 45, it appears that bronchitis is the special risk of lorry-drivers, tuberculosis of boot-and-shoe workers, and peptic ulcer of unskilled labourers. Asthma is relatively common in the upper social groups, particularly in youth, but other respiratory diseases tend to concentrate in the lower social groups. A study of old people in Dorset suggests that of the 37,000 living in private houses, 7400 are permanently incapacitated, and an equal number are likely soon to have major breakdowns. About 60% of the permanently incapacitated are being adequately looked after by relations or others, and it is estimated that the home-help service could supply all that is needed for half the remainder.

Self-contained surveys have proved more difficult to complete. This method, which entails the repeated examination of the same persons, accurate recording of detail, and strict observance of the rules of procedure, has in practice demanded more resources than a small institute could command. Clinical work on the student health survey ended in 1950, and by the end of this year 8 papers will have been published on this study. The child-health survey is the only other self-contained study still on hand, and is now in its eighth year. If the original plan is followed the collection of clinical, social, and radiological data will be continued until September, 1953. Some new standards for assessing weight in infancy have been devised which take account of parental size in normal expectations. These standards reduce to negligible proportions the effect on weight gain of low social status, lack of household amenities, and poor mothercraft, and enhance the weight differences of bottle-fed and breast-fed babies. New standards of skeletal maturity, based on serial radiographs of the hands and knees, have shown that several features which have hitherto been regarded as evidence of disease are in fact normal variants. Such findings are good evidence that the candle lighted at the institute by Ryle had a penetrating beam. It is to be hoped that the flame will not be quite extinguished.

NOBEL LAUREATE

THE Nobel prize for chemistry for 1952 has been awarded to Mr. A. J. P. Martin, PH.D., F.R.S., and Mr. R. L. M. Synge, SC.D., F.R.S., for the work on chromatography which they carried out together at Cambridge University and at the Wool Industries Research Association's laboratories. Dr. Martin is now a member of the scientific staff of the National Institute for Medical Research, Mill Hill, and Dr. Synge, who was formerly biochemist to the Lister Institute in London, now holds the same post at the Rowett Research Institute, Aberdeenshire. Their invention of partition chromatography, which has made possible the separation and identification of amino-acids, has been of special value to protein chemistry, for the method can be used not only to recognise and isolate the new amino-acids from natural sources but also to investigate the amino-acid constitution of complete proteins.

Air Vice-Marshal Sir DAVID MUNRO died at Halton, Bucks, on Nov. 8, at the age of 74. A former director of the R.A.F. Medical Services, he was also for twelve years secretary to the Industrial Health Research Board.

Mr. J. E. STACEY, a former vice-president of the Royal College of Obstetricians and Gynæcologists and senior surgeon to the Jessop Hospital for Women, Sheffield, died on Nov. 9.

Mr. J. T. EDWARDS, D.SC., who died on Nov. 6, was from 1921 to 1929 director of the Imperial Bacteriological Laboratory (Indian Institute of Veterinary Research) where his studies on the immunisation of cattle against rinderpest were begun. Later in this country as a member of the Foot and Mouth Disease Committee he worked at the Lister Institute and at the Pirbright Research Station.

Points of View

WISDOM IS NOT ENOUGH

REFLECTIONS ON THE ART AND SCIENCE OF MEDICINE *

Robert Platt
M.D. Sheff., M.Sc. Manc., F.R.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF MANCHESTER

Some clinical problems can be solved by knowledge, some by experience, and some by understanding. The application of these three qualities has come to be known as clinical instinct or clinical wisdom.

Coarctation of the aorta is an example of a disorder which is frequently undiagnosed. In other words, knowledgeable physicians of all ages delight to make the diagnosis for the first time in patients who have already been seen by a number of other doctors, some of them highly qualified and experienced. In most cases the diagnosis presents no difficulty. Only *knowledge* is really required. Knowledge that such a condition may occur, of the type of person in whom coarctation may be found, of its physical signs, and of the means by which the diagnosis, once suspected, may be confirmed. The diagnosis is as likely to be made by a young enthusiast as by an older man of long training.

Experience tells more in the assessment of a clinical problem, and the weighing of clinical evidence. It is not a quality confined to the elderly, however; for what we mean by experience in this sense is really the ability to profit by experience, and that is a thing which some men never achieve.

As an example of a clinical problem in which experience rather than knowledge was brought to bear I will cite a case about which a doctor telephoned to me one evening many years ago. He would not, by ordinary standards be considered a good doctor, if only because his devotion to alcohol was often more evident than his devotion to his patients. On this particular occasion I did not wish to be called out, and as he had given me very little information about the patient I suggested that I might meet him the following morning. Then he said in a rather thick voice "you please yourself, but he is cold and he is sweating"; and I said "I'll come." The voice was that of an alcoholic but the wisdom was that of a clinician. (For those who like to know the end of a story I may say that the patient had cardiac infarction.)

The antithesis of the good clinician, the man who has not profited by his experience, is to me exemplified by the physician who is obsessed by the tangible in medicine—a radiograph showing gallstones, or a high blood-pressure, or an enlarged liver, to the neglect of the subtle indications of a clinical history. Leaving aside all the facts which with a little patience he can learn from the invalid himself, he seizes upon the evidence of the physical signs or of the radiologist or the laboratory, ignoring the discrepancy between them. He is right of course, in diagnosing gallstones, but they do not happen to be the cause of the patient's symptoms.

Physical signs can tell us only about the patient's body. The clue to his mind is the history: and since symptoms, being subjective, exist only in his mind, and it is usually symptoms not physical signs for which he seeks a cure, it is a pity to direct attention prematurely into channels which can give us only indirect information as to his state of disease.

The association of headache with high blood-pressure is a common one, but the fact of their association does not prove their dependence upon one another. Quite often it is the husband or the neighbours that are the cause of the headache. One would perhaps expect that a highly trained scientific mind, used to the interpretation of evidence, would be helpful in this process of assessing a clinical problem, but I have reluctantly to admit that such is not always the case. I have known more than one medical scientist fall repeatedly into errors of the kind that I have illustrated, though he would not tolerate the same logical fallacy in the laboratory. Perhaps it is the forensic rather than the scientific mind, because of its familiarity with the human element, which excels in this aspect of clinical medicine. F. M. R. Walshe[1] in fact makes a good point when he infers that it is perhaps logic rather than science that we should teach at the bedside, and in his unrivalled phraseology speaks of "the barren triumphs of technique over reason."

The third quality which is required of the clinician is that of *understanding*. This is probably more an inborn quality than the other two, for I refer to a true and sympathetic understanding and not (to quote Walshe[1] again) "the hollow formulæ of false solicitude which masquerade as humanity."

It is often required particularly at the beginning, when we are trying to assess the nature or essence of the problem, and again at the final summing-up when diagnosis, investigation, and treatment (in its restricted sense) are completed and we have to agree upon a way of life for the patient. I use the words "agree upon" deliberately, because such advice must always be the result of consultation and discussion. Rarely if ever should it be authoritarian, didactic, or given as an order. It is often our duty to point out to a patient the risk that he is taking—for instance by making a journey or by remaining at his work. It is never really within our competence to forbid him to take it. Some doctors seem to delight in ordering patients to give up all that they find most satisfying, be it work or alcohol; "be it of virtue or of mischief," as Francis Bacon would have said.

While we are on the subject of virtue and mischief in our patients' lives I would say that it is not our business as doctors to moralise, except perhaps about ourselves. It is not our duty to advise a burglar to give up burglary unless we feel that his particular occupational hazards are acting to the detriment of his health. (I have known one or two street bookmakers and tic-tac men who have developed an anxiety state clearly related to their occupations.) Our duties as citizens and as doctors often overlap and sometimes conflict, but we should at least try to distinguish between them.

SCIENTIFIC AIDS AND SCIENTIFIC METHOD

I have omitted from consideration, you may say, the clinical problem which can only be solved by medical science; but here we get into difficulties, for it has to be admitted that many men practise good medicine with little scientific knowledge. Science puts tools into the hands of the clinician; it is not necessary to understand optical theory to use an ophthalmoscope, or to be a physicist in order to interpret an X-ray photograph. Even laboratory reports may be intelligently used with little or no knowledge of how the tests have been performed. These refinements, essential to modern medical practice, are given to us by scientific discovery but are used by the clinician as an extension of what he can discover by his unaided senses. Moreover they must be so used; for if considered in isolation from the problem of the patient as a whole they can be misleading. Indeed it is one of the difficulties of the medical teacher, who hopes to inculcate scientific ways of thought into his students, that so much of the everyday work of medical practice can be done without any pretence to scientific thinking. The less interested student very soon begins to believe that a good deal of his scientific background is unnecessary—a belief which may even be encouraged by some of his teachers.

---

* From an address to the Manchester Medico-ethical Association on Oct. 9, 1952.

[1] *Lancet*, 1951, ii, 895.

There remain perhaps a few cases in which the diagnostic problem can be solved only by the use of the scientific method at the bedside—cases in which we must observe and record *the response of the patient to conditions* imposed upon him experimentally.

THE PSYCHIATRIST

Before leaving the subject of the practical art of medicine we might here make a short digression on the rôle of the psychiatrist. Truly it is his business to investigate human relationships and emotions, which form much of the material with which the art of medicine is intimately concerned; but like all specialists he is ill equipped to deal with the patient as a whole, and in my experience he is generally no better as a humanist, and no more skilful in the art of medicine than is the General Physician or Practitioner. It is his business to develop new techniques in the investigation and treatment of mental and emotional disorder, and to teach what he has learnt; but it would be a bad day indeed if he came to be regarded as the only person capable of dealing with human feeling; for the art which above all includes the ability to handle human beings must pervade all branches of our subject. It is as necessary in the aurist whose patients dread the threat of deafness as it is in the cardiologist whose patients fear for their lives.

TRAINING IN SCIENCE

Those who love the art and fear the science of medicine will no doubt approve of what I have said so far. Wherein then lies the need for training physicians in science to the extent which some of us try to do today?

First, I would say, the training is needed because scientific discipline is the antidote to a surfeit of the art of medicine, which, carried too far, degenerates into medical lifemanship. It is said that all power corrupts, and the power which a physician has to influence the lives of his patients is formidable indeed. Ideally, no antidote should be required, but the clinician who knows only the art and is unversed in scientific thought and method may end by deceiving not only his patients but himself. If he does so unwittingly he will soon become satisfied with standards which are less than the best, if wittingly he becomes a quack, albeit a highly qualified and experienced one. Self-deception is the sin against which scientific discipline protects. I have illustrated some of the pitfalls which beset the scientist at the bedside through neglect of appreciation of the human element, but his occasional ineptitudes are not to be compared with the pompous stupidity which neglect of scientific thinking makes possible in the clinician.

Secondly it is necessary to teach scientific methods in order that the efficient weapons against disease that are now in our hands shall not be misused. The means to solve most clinical problems are now available. It is a major error, for instance, to treat a patient suspected of pernicious anæmia without first establishing the diagnosis, if only because the diagnosis is thereby obscured and the answer, all-important to the patient, to the question of how long he must continue the treatment will not be known. The inculcation of more scientific thinking into the clinical student should prevent some of these misdemeanours which at present are being daily committed by our profession, and would in time greatly improve standards of medical practice. Moreover the new remedies are often themselves dangerous. To use them empirically without establishing a diagnosis is usually to run an unnecessary risk as well as to conceal the truth both from patient and doctor. Sometimes it is a risk which must be taken, but if so it should be *done deliberately after a full appreciation of the position.*

Thirdly, science is necessary for the advance of medicine. Some advances are still possible from the use of clinical methods alone, as the recent brilliant work on the surgery of mitral stenosis has shown; but these are subject to the law of diminishing returns, and we must look to the scientists for most of the major advances of the future. Unless clinicians *are prepared themselves* to engage in scientific investigation and experiment these advances cannot come. Only the clinician can appreciate the problem which disease presents, though he may require the help of an army of scientists to disclose its secrets. Surely he should be *a collaborator with them*, and will be a better man for taking part in the adventure.

Finally there is the satisfaction which scientific honesty, truth, logic, and method give, which can be an object in itself; and the thrill of discovery, however trivial and unimportant may be its *immediate implications.* It is fundamental to a university education that we should try to teach not only what to do and how to act, but the reasons for doing so. This is the essential distinction between such an education and a technical training. It is further *fundamental to a university that its teachers* should themselves be engaged in the advancement of knowledge and that its students should be in contact with the frontiers of knowledge, should learn the limitations of knowledge at the present day and should have *some contact, even though it be secondhand*, with research and discovery.

In the days of Osler there were still plenty of opportunities for the advancement of medical knowledge by the clinical methods of experience, observation, and record. Those *opportunities have narrowed very greatly* and pure clinical observation is no longer enough. It is fairly true to say that except in surgery, the great advances of the last thirty years have come from the science rather than the art, and even in surgery they have largely been made possible by the scientists, who have given surgery the benefit of antibiotics and modern anæsthesia.

CLINICAL RESEARCH

In a recent address Sir Cecil Wakeley *spoke of clinical* research as if it were simply a matter of keeping accurate records. If he has done this himself I am sure he has found his records very disappointing. Occasionally matters of great importance will come from them, but more often there is *little to be learnt which is not already* known—unless the records have been kept with an end in view, as part of a planned experiment. Records should be kept for purposes of record. They are useful if the patient returns, and they may be of historical interest. But neither clinical records nor *logic by themselves* can replace the experimental method in *clinical investigation* as Harvey knew a long time ago. Twenty years of record are useless in determining the importance (or otherwise) of potassium therapy in diabetic coma; for, until someone realises *that it may be of* interest, the serum-potassium is never estimated and therefore never recorded. Clinical experiment need not mean the subjection of patients to uncomfortable procedures of *doubtful* value or benefit. It means the planning of a line of action and the *recording of observations* designed to withstand critical analysis and give the answer to a clinical problem. It is an attitude of mind, and it includes the investigation of disordered function in disease *as well as the response* to therapy.

The practice of medicine is probably of as high a quality in this country as anywhere in the world, but in the advancement of medical knowledge we have been falling behind America and Scandinavia. In my view the honorary system has had a great deal to do with this slow rate of progress, and its recent abolition has come thirty years too late. British physicians have been too long content with a system which put all its emphasis on the art and practice and almost none upon the science. The result has been that some of our best men have never had time to make an adequate contribution to knowledge. And so when we hear voices raised against the inroad of science and stressing the need throughout to teach the art, we have first to ask whose voice it is that we hear and whether the plea is not partly one of self-justification. Who then should be the teachers of medicine? Should they be these whole-time professors who are sometimes thought to be lacking in the art or should they be drawn from those who have a rich experience of the practice of medicine? Obviously it is to the benefit of the medical student and of the school that there should be teachers of various kinds. As to whether the professor himself should be whole-time or engage in private practice, the answer is easy. There are only 24 hours in a day. A professor of medicine has four separate tasks and could quite easily spend his whole time on any one of them—teaching, research, administration, and hospital practice. It follows that he cannot possibly have time for private practice in addition, and that even without it, if he has a conscience, he is bound to feel continually inadequate to his task.

As to what kind of a man he should be the answer is also quite obvious. Medicine being a synthesis of art and science, he must be a man who is supremely competent at both. The only difficulty is that no such man exists, and so we have to make do with the best compromise that we can find. If he is primarily a clinician he must have a staff which is particularly strong on the scientific side; if primarily a researcher he must have strong clinical backing. Of one thing I am quite certain, that he must be a man whose opinion as a clinician his colleagues can respect, and that in the conflict of loyalties to which he will be daily exposed he must in the final issue put the welfare of his patients before anything else, because he has a fifth duty, which is to set a standard of doctoring.

I have the notion that ideally he should be a man whose father was a Fellow of the Royal Society and whose mother was on the stage—a synthesis of science and art. (Of course, he might inherit the wrong qualities from either side—the story of Bernard Shaw and Isadora Duncan is not unknown to me.)

THE DOCTOR'S GROWING RESPONSIBILITY

Before leaving the place of science in medicine I would like to touch upon a theme on which I have written before. It is that the responsibility which we shoulder increases with every new discovery. When there was no efficient treatment for meningitis it did not matter whether we made the diagnosis on the first day or the fifth. Today it may literally be of vital importance. The same responsibility concerns us in all that we do, with chronic illness as well as with acute. Advances in surgery are not solely the concern of the surgeon, but place a new responsibility on the practitioner to recognise the early stages of disease which may be amenable to the surgeon's newer skills. Advances in social services bring with them a responsibility again that they shall be properly and freely used by those in need of them.

THE NEW MEDICINE

It seems fantastic that one should today spend time in justifying the place of science in medicine, but it is clear from the writings of a few and the talk of many that such a justification is still required. Among the few I emphatically do not include Dr. Walshe, whose warning of the encroachment of technology on the Arts of Medicine is well warranted, and from whose Lloyd-Roberts lecture I have already quoted.

I was fortunate myself in being brought up in a university in which such a justification of the place of science in medicine would, in 1920, have been considered already unnecessary. By an act of Providence, the elderly purveyors of polypharmacy had all been recently eliminated by the operation of time from the medical staff of the Royal Infirmary at Sheffield, and when I qualified and later became a registrar my most senior colleagues were less than 20 years older than I. I realise now that the clinicians who influenced me most as a student and a young man were between 35 and 45. They had clinical wisdom in plenty, but they were also clearly conscious of the fact that the new medicine was something different from that which had been taught by their predecessors.

This is not to say that older men, if they keep in touch with young minds, cannot be at least equally inspiring; but with a subject advancing as rapidly as medicine it is increasingly difficult to keep pace as the years go on. Wisdom and experience increase and are valuable. I know that I can now talk on equal terms with some patients on whom for all my young man's knowledge I would have made little impression 20 years ago; but I know that it is at the sacrifice of something else, and something very important. Even if we try to keep up to date and learn the new electrocardiography and the biochemical intricacies of metabolic medicine, our knowledge of the basic sciences on which the medicine of today is built becomes more and more outdated. I will cast discretion to the winds and say that I doubt if any professor of medicine should be more than 55. Allow him as an act of grace a few more years to reap something of what he may have sown, and for the sake of continuity and for the benefit of any wisdom which may have come with maturity; but if he shows signs of believing that only those of maturer years can have sound judgment or practise good medicine, or if he begins to think that he is indispensable, or becomes too highly respected for anyone to dare to tell him the truth, and above all if he begins to think that his wisdom and experience more than compensate for his inability to grasp the significance of new discovery and to keep up with new knowledge, get rid of him. It is possible to practise good medicine at a considerable age, but not to be an efficient teacher and trainer of the coming generation, or the leader of a team of medical investigators.

ARTIST AND RATIONALIST

In the title of this address and throughout its substance I have laid myself wide open to attack from those who like definitions and semantic niceties. I have avoided defining wisdom, art, and science, and in a subject like medicine it is quite impossible to set exact boundaries between them. Logic is the basis of science, but so it is also of good clinical skill: it is the link between the two. You may say also that I am being illogical or unscientific in discussing matters in terms which I have not defined, but I am not discussing the material of science. It is a good deal easier to define sodium than it is to define wisdom. I can only say that I hope that the sense in which I have used my terms has been clear from the context.

If there seems to me to be no essential conflict between the art and science of medicine, then equally there seems no conflict in trying to be at the same time both artist and rationalist in one's personal outlook in and out of medicine. Bertrand Russell in his recent defence of rationality[2] points out that reason signifies a choice of the right means to an end that you wish to achieve. Reason does not dictate the end itself. Reason is not the driving force which is supplied we know not whence—the inspiration of the artist. I would personally go a little further. While I accept the fact that emotional and irrational forces are the main determinants of our aims, both good and bad, I think reason should and can influence the choice of the ends towards which our endeavour is directed. Rationalism to me means above all the attempt to avoid self-deception, an attitude of mind which compels one to ask equally of oneself or another "what are the reasons for your belief?" and expect a logical answer, whether we are discussing psychiatry, theology, or the treatment of pneumonia; and in questions where as yet no logical answer is possible the rationalist is much happier with an honest agnosticism than with a statement of faith; for the former leaves the whole matter open for further investigation and research whereas the latter closes the door to inquiry and erects an emotional barrier between believer and unbeliever.

---

[2] *Listener*, Sept. 25, 1952, p. 495.

Five years ago I was stimulated by hearing Bertrand Russell broadcast in a series entitled "What I Believe."[3] Most of his opinions spring ultimately, he said, from admiration for two qualities: kindly feeling and veracity. To cultivate them it is not necessary to appeal to supernatural authority but only to have a general wish for happiness. It is surely not irrational to believe that the world would be a better place if these two virtues were more generally practised. In them I saw again the art and science of medicine, in kindness and veracity. The wish to help and above all to understand the human being in distress, the discipline to withstand all temptation to depart from scientific accuracy, and the determination to advance knowledge by the methods of science which are ultimately concerned only with the search for truth.

* * *

It is dangerous for a man to speak in public upon his aims and ideals, for he soon finds himself only too vulnerable. If occasionally he dares to do so it is not to be inferred that he has any conviction that he has lived up to them.

EPIDEMIC HÆMORRHAGIC FEVER

ALAN J. ROWE
CAPTAIN, R.A.M.C.

BEFORE June, 1950, when epidemic hæmorrhagic fever (E.H.F.) was first encountered by United Nations forces in Korea, this disease was unknown to the Western world. The only references to it in English were a few paragraphs in two official reports based on information collected from the Japanese in 1946 (Mayer 1952a).

When the first cases occurred among United Nations troops in Korea, the disease was thought to be one never before recorded, but investigations by the Americans indicated that it was similar to a hæmorrhagic disease known to the Japanese during their occupation of Manchuria. It was later established that the condition described by the Japanese was exactly the same as the disease in Korea (Beard 1952, Mayer 1952a). Further studies by Mayer (1951) showed a striking similarity between E.H.F. and a disease known to the Russians as hæmorrhagic nephrosonephritis.

HISTORY

Little is known about outbreaks of E.H.F. before those recorded by the Japanese and Russians, but Mayer quotes inhabitants of Manchuria (including doctors) who said that the disease has been endemic there for many years. The first Japanese account, written in 1939, tells of an outbreak in the Songo district of Northern Manchuria. Many different names were given to the disease depending on the district involved—e.g. Songo fever, Kokka disease, and Korin fever. Various workers in Japan showed that all these diseases were identical, and in 1942 the disease was renamed febris hæmorrhagica epidemica, the anglicised version of which has now been adopted in this country and the United States. Ibuki (quoted by Beard 1952) later established that E.H.F. had broken out among Japanese troops serving in Northern Manchuria in 1935, the illness having been diagnosed at the time as purpura, hæmorrhagic typhus, or scarlet fever. All the Japanese cases were found in swampy areas or near rivers, and it was in this type of country that the disease first attacked United Nations troops.

Mayer has drawn attention to certain communicable diseases described by the Russians. Several types of hæmorrhagic communicable disease (presumed to be virus infections) are known in Russia—e.g., Omsk hæmorrhagic fever, Crimean hæmorrhagic fever, and the hæmorrhagic fever described by Katsenovich and Itskovich (1950)—but the true E.H.F. seems to be limited to Far Eastern Russia. It was first described in 1934 under the name Churilov's disease, but this title was later changed to hæmorrhagic nephrosonephritis. Further accounts of hæmorrhagic nephrosonephritis have been given by Bilibin (1950) and Viskovsky (1951).

ÆTIOLOGY

The ætiology of E.H.F. is uncertain. Clinically there is some resemblance between it and Weil's disease, and some early workers reported thread-like objects in the blood, suggesting that a leptospira was possibly the cause. Tsygankov (1941), discussing infectious nephrosonephritis, also thought that it was a leptospiral infection.

The Japanese, on the other hand, regarded the disease as either viral or rickettsial in origin, and certainly the bulk of the evidence seems to be in favour of a virus. Kitano (1944) (quoted by Mayer 1952a and Beard 1952) reported that the virus of the Far Eastern type of E.H.F. could be isolated in the febrile stage of the disease, and that it passed through L_5, L_6, and L_9 Chamberland candles and through the EK Seitz filter. The disease has been reproduced in monkeys and human volunteers by inoculation of virus-containing material (Smorodintsev et al. 1944, quoted by Mayer 1952b). Viskovsky (1951) said that Smorodintsev had identified a virus as the cause of hæmorrhagic nephrosonephirtis in 1940.

Others have suggested that the mite, *Lælaps jettmari* Vitzthum, which is a parasite on the field-mouse, *Apodemus agrarius*, is responsible for transmitting the disease to man. *A. agrarius* usually lives in swampy areas and in the long grass on river banks, but it is not confined to damp places and may be found in forests. In Russia the Eastern vole, *Microtus michnoi*, may also carry the virus (Viskovsky 1951). Mayer (1952a) mentions some interesting experimental work with emulsions prepared from infected mites or from infected organs. Although inoculation of this material into monkeys and man will reproduce the disease, the Manchurian field-mouse and house-mouse show no visible effects from such inoculation. The Eastern vole, however, develops enlargement of the spleen and hæmorrhagic changes in various organs, although there is no selective involvement of the kidneys (Leibin 1947).

Although the disease is present all the year round in Manchuria, Korea, and Far Eastern Russia, there are some seasonal changes; in Korea the number of cases reaches a peak in the spring and the autumn, and Viskovsky (1951) records a similar seasonal distribution of hæmorrhagic nephrosonephritis.

DISTRIBUTION

E.H.F. does not seem to have spread throughout Manchuria and Far Eastern Russia. The southern and western parts of Manchuria are thought to be free of the disease, though endemic foci exist along the Korea-

Manchurian border. The Russians have reported it as far north as latitude 50° (Mayer 1952a and Viskovsky 1951). In Korea E.H.F. is mainly, but not entirely, confined to swampy ground and areas near rivers. Kater (1951) suggested that it was introduced into Korea from Manchuria by the Chinese Communist forces. Mayer (1952a) gives a detailed account of the distribution of E.H.F.

CLINICAL COURSE

The incubation period is from one to three weeks. Prodromal symptoms are not common, but fatigue, general malaise, and slight myalgia with "lumbago," mild fever (Nancekivell and Macdonald 1952), and diarrhœa (Beard 1952) may occur at this stage. However, the onset is usually abrupt, with high fever, chills, tremor, frontal headache, anorexia, nausea, and vomiting.

Mayer (1952a) describes three stages: (1) a febrile stage; (2) an afebrile stage, in which the hæmorrhagic tendency and signs of toxæmia appear; and (3) the convalescent stage. Nancekivell and Macdonald (1952) prefer four phases: (1) febrile; (2) shock; (3) oliguric; and (4) convalescent.

In the febrile stage the temperature may rise to 104°–105°F. The pyrexia usually persists for five to seven days, reaching its maximum after about forty-eight hours (in Siberia, one of the names given to E.H.F. is "six-day fever"). The temperature falls suddenly, but the severity of the symptoms does not diminish as the temperature falls—lysis paradoxicus (Kater 1951). During the febrile stage, nausea and vomiting are severe and may last about a week. The hæmorrhagic tendency gradually makes its appearance, and from about the third day onwards, morbilliform or linear petechiæ may be seen, especially in the skin of the neck and face. Hæmatemesis, bloody diarrhœa, hæmoptysis, and hæmaturia may appear as the hæmorrhagic state becomes more pronounced (Nancekivell and Macdonald 1952).

Hæmaturia is one of the most important symptoms and is a great help in differentiating E.H.F. from other similar hæmorrhagic infectious diseases. There is some degree of renal involvement in nearly all cases, and the urinary symptoms are one of the most characteristic features of this disease.

Another characteristic sign is the appearance of the face. From about the third day onwards the face becomes flushed, and by the seventh or eighth day subconjunctival hæmorrhages are common. The conjunctivæ may appear uniformly cherry-red in colour, and vision becomes blurred. Petechiæ are often present on the palate and pharynx (Nancekivell and Macdonald 1952).

By the time the second or "shock" phase has developed, the hæmorrhagic tendency is well established. In this stage the patient is afebrile; the pulse, which during the febrile stage often shows a relative bradycardia, becomes rapid and thready; and the systolic blood-pressure is low. The skin, which is dry in the first stage of the disease, becomes cold and sweaty. This phase lasts four to five days, and during this time oliguria develops and urine of low specific gravity is excreted. This phase ends with a sudden diuresis and the production of large volumes of urine of low specific gravity, or it may progress to anuria.

Among other symptoms, backache is sometimes quite severe and may persist for several weeks; Beard (1952) mentions a peculiar characteristic odour about these patients; and hiccup may be very troublesome and persistent. The central nervous system can be affected and symptoms such as restlessness, insomnia, photophobia, and mania may develop. The Russians describe a meningo-encephalitic form of E.H.F. which usually ends in coma and death (Mayer 1952a, Tsygankov 1941). The liver and spleen are sometimes slightly enlarged and tender. but jaundice is rare (Kater 1951). Ruptured spleen has been recorded by Monroe (1952). The lymph-glands may be enlarged and tender, especially those of the cervical and axillary regions. Gastro-intestinal symptoms are emphasised by the Russians (Viskovsky 1951).

Recovery usually begins towards the end of the second week. After the sudden diuresis, the concentrating power of the kidneys recovers with consequent increase in the specific gravity of the urine. In fatal cases, death usually occurs within forty-eight hours of the fall of temperature.

Complications include bronchopneumonia, orchitis, pancreatitis, hepatitis, and encephalitis, but the commonest is parotitis, which, it has been estimated, occurs in 3–4% of cases.

Convalescence is usually rapid, except in the severe cases where renal symptoms and failure to gain weight may continue for some time. The Japanese report recurrent bouts of temperature and a mild hæmorrhagic tendency A follow-up of British cases for periods up to nine months has shown that most of the urinary symptoms resolve completely. In a series of 9 cases only 2 showed any evidence of diminution in renal function after six and nine months respectively, and in both cases there was continued improvement.

LABORATORY INVESTIGATIONS

Occasionally there is an initial leucopenia, although the white-cell count is usually normal early in the disease. The count rises fairly rapidly to 30,000–50,000 cells per c.mm., and occasionally much higher. There is always a shift to the left, mainly in the granulocyte series. This leucocytosis of E.H.F. and hæmorrhagic nephrosonephritis is in striking contrast to the leucopenia found in the other Russian hæmorrhagic fevers already mentioned (Bilibin 1950).

The platelet-count falls to 40,000–100,000 per c.mm. during the hæmorrhagic period. but rapidly returns to normal on recovery. The capillary fragility test becomes positive early in the disease and the prothrombin-time is sometimes prolonged, but the bleeding-time is usually normal.

The red-cell count and the hæmoglobin level are normal unless there is severe hæmorrhage. Albuminuria, which may be very heavy, occurs early in the disease, and is accompanied by granular casts and red cells. Microscopic hæmaturia is a constant feature of E.H.F.

The cerebrospinal fluid is usually normal. The Takata-Ara test is usually positive at the height of the fever (Mayer 1952a), but such serological tests as the Weil-Felix, Widal, and Wassermann are negative.

The level of non-protein nitrogen in the blood is raised during the disease, and falls with improvement in renal function. The level of reduced vitamin C is below normal, and the Thorne test (A.C.T.H.) may produce no response (Nancekivell and Macdonald 1952).

TREATMENT

Treatment is almost entirely symptomatic; antibiotics and chemotherapeutic agents have been tried, but they are of value only if secondary infection occurs. Convalescent serum has been used, and is said to help if given during the first two or three days. Otherwise treatment consists in intravenous infusion to maintain fluid and electrolyte balance, vitamin K, vitamin C, and blood-transfusion where necessary.

PATHOLOGY

Accounts of the morbid anatomy of E.H.F. are given by Kater, Beard, and Mayer. The most important pathological finding is the widespread involvement of the capillary circulation; the peripheral vessels all over the body are dilated and there is hyperæmia with purpuric hæmorrhages. Perivascular cuffing is found in several organs (Mayer 1952a), and Viskovsky (1951) mentions specific changes in the endothelial layers of the capillaries. The outstanding changes are found in the kidneys, which may swell to twice their normal size; rupture from severe hæmorrhage has been recorded (Beard 1952). Macroscopically the medulla is bright red, and the cortex pale and cloudy. Microscopically, hæmorrhage is greatest at the corticomedullary junction, and is quite severe in the rest of the medulla.

As well as hæmorrhage in the heart muscle, hyaline degeneration may be found, and Beard records dilatation of the right auricle of the heart. The liver and spleen are less enlarged than the kidney, but they may show albuminous degeneration and hæmorrhages. Reactive hyperplasia of the reticulo-endothelial system may develop in the spleen. In the brain, both parenchymatous and meningeal capillaries are affected, and hæmorrhage into the parenchyma, particularly in the region of the pituitary gland, sometimes occurs. Pituitary hæmorrhage has been a common post-mortem finding and is regarded by some as highly significant; sometimes the nerve-cells show degenerative changes. Hæmorrhage into the suprarenals has been recorded.

Examination of necropsy material from 2 British cases showed no specific lesions other than those associated with a hæmorrhagic diathesis. In one case pituitary hæmorrhage was very marked, and in both cases the medulla of the kidney was grossly disorganised by hæmorrhage. The glomeruli, however, showed few signs of hæmorrhage.

PROGNOSIS

It is difficult to give a prognosis in the early stages of E.H.F.; for, although the temperature may fall, the disease may become more severe and collapse can occur at any time. The Japanese record a mortality-rate of 30%, but the mortality-rate in the United Nations series varied from 8 to 16%.

DIFFERENTIAL DIAGNOSIS

This disease has been incorrectly diagnosed as Weil's disease, epidemic typhus, scrub typhus, purpura, and hæmorrhagic smallpox. In Russia the group of hæmorrhagic diseases referred to above, such as Crimean fever, have also to be excluded.

I wish to thank the Director-General, Army Medical Services, for permission to publish this paper, and Brigadier A. Sachs, Director of Pathology to the Army, for his encouragement. My thanks are also due to Major J. B. Neal, R.A.M.C., for providing access to histological material initially submitted to the Army Tumour Registry by Captain A. Knudsen, R.A.M.C.; and also to Major J. Kilner, R.A.M.C.

FELLOWSHIP FOR FREEDOM IN MEDICINE

THE third annual meeting of the Fellowship for Freedom in Medicine was held in London on Nov. 8, under the chairmanship of Lord Horder.

Dr. E. C. WARNER, the hon. secretary, said that the membership of 3293 was almost the same as in the previous year. Publicity had included the printing of four bulletins and of two broadsheets entitled "How to improve the hospital service" and "Why private patients should be entitled to receive essential drugs on the same terms as N.H.S. patients." The fellowship had also conducted an inquiry which showed that there was wide support for returning the right of buying and selling the goodwill of medical practices to those who wished to regain this right.

The reports of five subcommittees of the fellowship were discussed and adopted. Arising out of this, two resolutions were passed, nem con.: "That this meeting deplores the method by which the G.M.S. Committee of the B.M.A. presented the findings of the Working Party, which has led to misunderstanding and disagreement in the profession"; and "That this meeting calls for a re-examination of the unsatisfactory method of distribution of the Central Pool, with particular reference to the position of the small-list doctor."

Mr. E. J. R. BURROUGH presented the proposed terms of reference of the lay associate members, and gave an account of how they could best further the interests of the fellowship. The terms of reference were approved by the meeting.

Lord HORDER, speaking as chairman, said that the most outstanding fact about the fellowship's work was its influence on current thought about the National Health Service. Criticisms of the N.H.S. which the fellowship was making three or even four years ago, and which seemed at the time to go unheeded, were now quoted by the press as commonplace. The fellowship had been criticised for not producing spectacular results: it had never set out to do this, but aimed at changing the climate of opinion. Who could doubt that the climate of opinion had changed—and not only among the public? "Perhaps it would be egregious to suggest we have influenced the Minister, and yet is it only an accident that, if you read the speech of the Minister which we print in our current bulletin, you will be struck by the close resemblance between the aims and objects of the fellowship and the present declared policy of the Government?" In the counsels of the B.M.A. the fellowship had been the first to press for the principles of arbitration in settling the vexed matter of the general practitioners' long-delayed remuneration betterment factor: even the rider to the Working Party's report, which secured some measure of justice for the small-list doctor, was the result of pressure by the fellowship. There remained a great deal to do—expressed simply this meant lifting the health services of the nation right out of the political field. The administrator was essential to our purpose: the politician was not only unessential, he was an incubus. When the fellowship started four years ago, it had set out to achieve what to many in the profession seemed wholly unattainable. "They said that Mr. Bevan's travesty of a National Health Service was an accomplished fact and that we must hug our chains. But we believed that the freedom of our profession was something worth fighting for; and our faith is being justified. One by one we are casting off our fetters." Lord Horder concluded by appealing to all who recognised the work of the fellowship to join: doubling the present membership would double its influence and double the amount of work that could be done and was crying out to be done.

Reconstruction

DO'S AND DON'TS FOR HOSPITAL PLANNERS

IN his recent book, *Background to Hospital Planning*[1] Prof. H. W. C. Vines shares with his readers the experience he has gained in studying hospital design and in helping to plan the new Charing Cross Hospital. His musings on and around the purpose and function of a hospital cover such topics as the work, size, patients, and staff of acute general hospitals; the care of outpatients; inpatients and the planning of the main special departments and services; the special problems of teaching hospitals; and the changes the next hundred years will bring. But he has written a book to stimulate thought and further investigation of hospital planning in its wider aspects rather than to serve as a vade-mecum for the architect on hospital architecture.

One of the important problems he considers is whether all specialties, except mental illness, should be included within the general hospital, so that every sick person may have at his disposal the full range of facilities of a general hospital. The evolution of the medical services in this country has led to the building of a considerable number of special hospitals, particularly by the local authorities; but as Professor Vines points out, some of these have been closed, and others are ceasing to be special hospitals. The training of nurses and the difficulties of staffing have speeded the process of including special beds, such as those for tuberculosis and chronic patients, within the ambit of the general hospital, and also of bringing acute general cases into the larger special hospitals, more particularly those designed, but no longer needed to the same extent, for the treatment of communicable diseases.

THE RIGHT SIZE

Professor Vines also discusses what is the best size for an acute general hospital. His own opinion is that 800 beds is a reasonable maximum, with a lower limit of 200 for acute general work. But he believes that there is also a place for the smaller hospital, down to fewer than 100 beds, staffed by general practitioners with visiting consultants. He advises that in chronic wards the beds should be spaced more widely than in acute wards, giving as one reason the fact that the patient is generally encouraged to get up as much as possible. But might it not be preferable to meet this need, even when adapting existing buildings, by providing more day accommodation—warm, comfortable, and homely—even at cost of economies in bed space?

In planning general hospitals the question always arises what provisions should be made for future expansion. Professor Vines leaves this as a moot point, but on the whole he is in favour of building a hospital only slightly larger than the immediate need demands, and then, if necessary in the more distant future, building a second hospital when natural shifts of population may show a different site to be more suitable.

THE PATIENT

Professor Vines has so many sensible things to say about the patient's place in the hospital that one is tempted to quote him at length.

> "The patient, the doctor and the nurse together form the elemental unit of medical care in the hospital, the home, or on the battlefield; like peace, they are 'one and indivisible,' for if there is no patient, the other two have no function. In the home, the patient lives in his own house and is fed and generally serviced by his own family; the nurse may sometimes stay in the house or may come in daily, and the doctor, too, may visit daily or less often. This unit requires the minimum of services, the State is put to a minimum of expenditure, and if the patient is not too seriously ill, this arrangement of the unit is satisfactory to his well-being. But both doctor and nurse can serve more than one patient, and if for any reason it is thought desirable to assemble a number of these simple units into one place, a building is erected or adapted for the purpose and the hospital is born. The patients are now separated from their homes and families so that integrated services become immediately necessary to provide food, treatment and hygiene for them and to light, heat and clean the building. In order to arrange these services efficiently and with economy, it has been usual to set up an administrative body, which is therefore but indirectly concerned with patient-care.
>
> "In such a way the patient becomes the most important person in the hospital, for he is the *raison d'être* of the institution and everyone else is there to serve him. When it comes to planning a hospital, everything should be made to centre around the patient, but quite often one finds that the convenience of the staff creeps into first place, and sometimes indeed it seems as though the patients had been put in as an afterthought. Rationally, the first element of the hospital should be patient-care, and next to that will come services, which provide all those things necessary, not only for the patient, but also for the staff in whose care the patient is. These two elements are linked together by a third, communications, used in the broadest sense of the routes and means of providing services. . . . I propose to regard the hospital as being built up on these three foundation stones, patient-care, services, and communications."

He argues that the mistake of planning for administrative tidiness rather than for the care of patients leads not only to difficulties in administration but also to unsatisfactory conditions for patients and staff.

> "It is reasonable for the patient entering the hospital to assume that all the facilities of the hospital will be at his disposal with a minimum of inconvenience, or even discomfort, to himself and that they will be adequate to deal with any eventuality which may arise in his case. If the buildings are well-sited and the departments have easy access to each other, the patient, being disturbed the less, will have the greater confidence in the hospital and it will be to him. a member of the public, a 'good' hospital."

This leads Professor Vines to a consideration of communications, which he defines as all those methods by which information, materials, and people move from one part of the hospital to another. In discussing their rôle in saving time and reducing the use of labour he justly points out that they require more study than they have yet had in this country. In particular, lifts have not yet been fully recognised as vertical corridors, but are still deprecated at times as an expensive way of pandering to laziness. Is there some vestigial puritanism here? There should be separate lifts for the patient in bed, for personnel (including patients in wheel-chairs) and for service; Professor Vines would provide a fourth to be reserved for food, with openings into the kitchen and the ward-kitchen only. If this lift were large enough to accommodate a food trolley, it would involve radical replanning of many existing ward-kitchens.

He also thinks that we have not given enough thought to the lighting of sickrooms and service rooms:

> "While we are beginning to take some care to place the patients' beds parallel with the windows and to provide night lamps at skirting-board level so that the patients shall not be worried by glare, it is curious that so little has been done, in this country or abroad, to improve the almost invariable system of lighting rooms from one or more central points in the ceiling. In the darker wards of city hospitals, as for instance in London, these lights shine down on the patients' faces for hours on end in the winter months; by contrast, in the service rooms where equipment, sinks, benches, and so forth are usually sited round the walls, the nurses and assistants work perpetually in their own shadows. It is time that we sublimated the chandelier-complex from which we have suffered so long and devised room-lighting so as to give a service of maximum efficiency and to bear a positive relationship to the work for which it is needed. There is still room for a good deal of research on the general lighting of sickrooms and

---

[1] London: Faber & Faber. 1952. Pp. 188. 30s.

service rooms, on reading lamps for patients at the bed-head and on the diffuse lighting of the whole bed without any distortion of colour, so necessary for the medical examination of the patient."

For the planner other people's mistakes may be almost as valuable as their successes, and the following warning list which Professor Vines has compiled is worthy of study:

"Inadequate provision of w.c.s for ward patients, to cater for the practice of getting patients out of bed earlier.
Insufficient or absent air-conditioning in operating suites.
The omission of piped oxygen and suction services.
The omission of the pneumatic tube services.
The scattering of lifts.
Insufficient cupboard space for storage in theatre suites and ward units.
Planning the entrance to the hospital for emergency cases too far from the main theatres and administrative offices.
Absence of an 'interview' room for relatives' use in the ward areas.
Planning linen and rubbish chutes too close so that confusion of their use arose."

HOSPITAL AS TEACHER

Looking into the future, Professor Vines says that, with the continuing improvement of the health of the people, thanks to better social conditions and proper education, there will not be the same call upon large general hospitals. In their place he sees a group of consultant outpatient clinics with a small number of beds. These outpatient clinics should be designed so as to be easily refitted internally; if the demand for beds decreases, or the advance in medical treatment necessitates the use of bedrooms as technical rooms, it should be possible to adapt the accommodation without major structural alteration.

But if in the future the hospital's responsibility for the practice of curative medicine decreases, Professor Vines believes that its responsibility for preventive medicine will increase.

"Apart from the curative treatment of the already ill, the acute hospital, as part of the local community, should now be developing a functional part in the prevention of disease, as in the more distant future its activities in this field may have to be considerable. Modern methods of treatment demand increasingly early diagnosis of illness in order to be fully effective and it is in the hospitals that methods of early diagnosis are likely to be developed and applied. There is then an increasing approach towards real preventive medicine as applied to the individual in contrast to sanitary preventive medicine, which applies rather to the masses. The hospital should be a centre of education of the local practitioners in this aspect of medicine, which is going to become increasingly important.' Indeed, the hospital has a large educative function to play in any community. Some hospitals are specifically concerned with the training of medical students or doctors; a far larger number are schools for the training of nurses or midwives; and others act as technical training centres for radiographers, almoners, dietitians, physiotherapists and so on. Intimately mixed with the daily routine of the hospital, there is the simple education of the patient in how to keep healthy, of the young mother in how to manage her baby or what she should do with her difficult child, a thousand problems dealt with by the nursing and medical staffs every day. And this leads on even to the teaching of the staff itself in what are called 'human relations' composed so largely of toleration, forbearance, and good sense. So the educative function of the hospital is wide, *ranging from professional technicalities almost to a philosophy* of life."

Medicine and the Law

Matrimonial Desertion and Mental Capacity

DIFFICULTIES arise in the Divorce Court when a petitioning spouse alleges desertion and the respondent spouse is a patient in a mental hospital. Desertion presupposes the *animus deserendi*, the intention to desert; if a party is of unsound mind, how can he or she form that intention?

In Keeley *v.* Keeley[1] it appeared that a wife had entered a mental hospital as a voluntary patient in 1941 and had remained there ever since. She was said to have suffered from the delusion that her husband was unfaithful and was poisoning her. During one of his visits to her, the husband had in 1943 asked her to return home, thinking that she had recovered. She refused, saying that she was quite happy where she was. He did not renew his request. In 1951 his solicitors invited the opinion of the medical superintendent of the hospital as to her capacity to form the intention to desert. The reply was that she was capable of making a reasonable decision to desert if she wished. At the trial he testified that though, as a voluntary patient, she was entitled to leave the hospital after 72 hours' notice, her condition was such that, if she did so, she would almost certainly be certified insane either on discharge or soon after. The Divorce Commissioner thereupon dismissed the husband's petition, on the ground that the wife was not, at the material time, capable of forming the intention to desert.

The Court of Appeal has allowed the husband's appeal and has granted him his decree, though with the caution that the case must be regarded as having depended on its own special facts. Reference was made to a decision of the House of Lords in May, 1951, in Crowther *v.* Crowther, where the husband had for the statutory period of three years been an inmate of a mental home under a reception order. It was there held that the court was not entitled to infer continued desertion from an intention shown in the pre-certification and post-certification periods, if the petitioner did not establish that the respondent spouse retained the mental capacity requisite for an intention to desert, or if no evidence was offered. The trial judge and the Court of Appeal had refused the wife her decree on the ground that the husband had been incapable of having an *animus deserendi* during the three years of the reception order. The House of Lords took a different view. There was, they said, no irrebuttable presumption that the desertion had been terminated by the mental incapacity; the petitioner was entitled to produce evidence that the respondent remained mentally capable of an intention to desert. Lord Oaksey went so far as to say that, once the original desertion was proved, the onus was transferred to the deserting spouse to prove an intention to resume cohabitation. Applying the Crowther decision to the Keeley case, the Court of Appeal held that the husband had succeeded; the evidence of the medical superintendent and other witnesses showed that the wife was perfectly capable, despite her hallucinations (which seemed in part to have disappeared), of making a reasonable decision about returning to her husband.

Desertion as a ground of divorce must be, under the Herbert Act of 1937 (now consolidated in the Matrimonial Causes Act, 1950), not only for three years but also "without cause." The Court of Appeal in the Keeley case seemed to think that "without cause" could hardly be established where a party was affected by illness which compelled residence in hospital for the three-year period. The position would be the same whether the illness was heart-disease or insanity. In any future litigation, if that question arose, the material allegations would have to be specifically pleaded and argued and the evidence considered. If, for instance, a wife remained in a mental hospital as a voluntary patient on medical advice in the interests of her health, the court might have to consider evidence whether that was the reason for her not returning to her husband or whether she remained there because she did not wish to return to him. It might even be argued in some future case that the patient was remaining in an institution in the public interest. That kind of speculation, however, the Court of Appeal left to be dealt with when the point arises.

Suicide and Temporary Insanity

Two coroners have lately been referring to the form of verdict which associates suicide with unsound mind. The Birmingham city coroner, discussing "fictitious verdicts" before a lay audience,[1] expressed the view that people who take their lives are not of unsound mind. "They are simply suffering from a sick mind in the same way that people have a sick heart or a sick lung." Coroners, he said, hated this question of suicide verdicts, but had no alternative. A finding of felo-de-se (suicide while of sound mind) left the dead man's family with the stigma of criminality; a finding of "suicide while of unsound mind" left it with the stigma of insanity. This was quite wrong; the speaker wished some other verdict could be substituted, such as the simple word "suicide." On the other hand the Bath coroner,[2] recording a finding that a 65-year-old man had died from coal-gas poisoning self-inflicted "while the balance of his mind was disturbed," denied that such verdicts were fictitious. They were, he declared, of respectable antiquity; he recalled the conversation of the grave-diggers about the death of Ophelia in the fifth Act of *Hamlet*.

The 1910 report of the Departmental Committee on Coroners might have been quoted in support of the Birmingham coroner's view. It recommended the abolition of the verdict of felo-de-se. "The only effect of retaining this verdict," said the committee, "is to induce juries to find a verdict of temporary insanity without any evidence to justify it." When the same committee, reconstituted with Lord Wright as chairman, reported in 1936, they recommended that where the deceased had died by his own hand there should be no inquiry into the state of his mind (except so far as it might throw light on the question whether he took his own life) and the verdict should make no reference to his state of mind. The official forms appended to the Coroners Rules of 1927 continue to use the formula (associated in the statute-book with the Infanticide Act) "while the balance of his mind was disturbed." If fresh legislation be needed to carry out the recommendations of the Wright Committee, perhaps some member of Parliament will bear the matter in mind if he is lucky in the ballot for private members' Bills.

According to the Criminal Statistics for 1951, the suicide figures are dropping: there were 4282 in 1951 as against 4324 in 1950. There were more male suicides than female (2675 men and 1607 women); but more women took their lives in 1951 than in the previous year (1607 against 1555). If the statistics show a decrease, the latest total is still amply sufficient to make the form of verdict important. As the Wright Committee's report reminded its readers, the felony of self-murder involved forfeiture of the dead man's property to the Crown down to the year 1870 when the Forfeiture Act was passed. And as recently as 1882 Parliament was formally and finally forbidding coroners to direct that the body of a suicide should be interred in a public highway or have a stake driven through it. Thenceforth a suicide's remains could be buried in the parish churchyard as if there had been no verdict of felo-de-se against him; they could at last be assured of what the Second Grave-digger called "Christian burial." These are comparatively recent dates and folk memory is tenacious. Has the time arrived for a third Departmental Committee on Coroners, to persuade the Legislature to abolish an embarrassing verdict?

In England Now

A Running Commentary by Peripatetic Correspondents

EMPIRE-BUILDING we call it in these parts, when one specialty enlarges its territory at the expense of its neighbours. Thoracic surgeon and neurosurgeon must carve out their domains from the body of general surgery. That is understood, but they are less easily forgiven when they do it by snaffling the beds that the potential gerontologist had his eye on. In pædiatrics we know all about this cut-and-thrust. Have we not made splendid gains in the debatable land of the newborn period, and even, here and there, got our hooks on the children with infectious fevers? Of course we have not always been able to defend our own borders against acquisitive moss-troopers such as the covetous cardiologist. A year or two ago I read with foreboding an article called "A Psychiatrist looks at the Newborn." Imagine then my elation when I found last week a reference to a paper on Neonatal Morality. Is this the counterblast of the pædiatrician? "Hands off the newborn! We can deal with his twisted psyche." I have yet to look it up, but I fear a misprint.

* * *

When the World Conference on Medical Education opens in London next year I hope that evidence will be taken from ageing and aged practitioners and specialists who have made a success of their profession despite the many important facts and theories they have forgotten.

Speaking for myself, I am regarded as a successful man, with a well-balanced judgment, a good manner, and the ability to inspire confidence. Yet if ever I knew the origin and insertion of the peroneus longus or the puzzling components of the brachial plexus, I have long forgotten them. Though I remember the mnemonics with which I sailed through my examinations, I cannot recall what they stood for. Weird and wonderful things they were—works of genius, forged in lonely lodgings, and handed down from generation to generation, like the ancient ballads. In my youth I studied with courage and avidity the motley crowd of medical curiosities I found in the wards. But I have never met them since, and I take comfort in the thought that with the rapid advance in living they have disappeared.

In this nostalgic concern for the student I speak as a specialist, and as such I must affirm that it is easier to become a specialist than it is to graduate in medicine. After all, the budding specialist knows what to jettison and usually he does it in truck-loads, but the poor student doesn't know what to get rid of. If I am asked to give evidence at the World Conference, I shall advise that students should be taught how to consult a Bradshaw. Then they will be able to pick out the principal trains for immediate attention, and leave the branch lines for intensive study when their journey there is really necessary.

* * *

First impressions are often important, and in my wanderings in recent months I have noted the words or inscriptions which caught my eye first at various hospitals. At one a notice in large letters proclaimed "Children under 14 years are not allowed to pass through the gates." I felt more comfortable at the hospital above whose door was carved in the stone "I was sick and ye visited me."

At another a quotation from William Blake's *Songs of Innocence* reminded me that "Where mercy, love and pity dwell there God is dwelling too."

* * *

"But darling it's a research job! But of course we're thrilled! Well, she is our only daughter. No, I'm not quite sure what she is going to work on. One can never tell, she might get a brainwave and discover something any minute. No, darling not too hard. They don't mind about the hours as long as the work is done. Of course, when she gets her brainwave then it will be quite different. Surely you remember the film about Mme. Curie? Well, that gives you some idea of research. Yes darling, just some idea . . ."

"Clarice? Oh darling, I've such a terrible disappointment, Binksie says she can't come to dinner. Work darling, gets back terribly late and often brings things home. Not a particular idea of hers. Old Bluebeard—no, darling, not his real name—well he's got to write an article for one of those medical magazines. Yes, terribly important. Well, Binksie has to find all the articles that other people have written on the same subject and pick out the important points. At the R.S.M. darling. Don't you know! It's the Royal Society of Medicine. Binksie goes there every day. Of course, it isn't always easy. Sometimes old Bluebeard asks for things he thinks he's read and hasn't really. Well you know the sort of thing. Says there's a certain article on a certain subject, by a certain man, in a certain paper and then, after Binksie has moved heaven and earth—or rather the R.S.M.—to find it, it turns out to be on a different subject—and often by a different man, and in a different paper. Oh yes, quite often. By the time she's got it old Bluebeard usually says he doesn't want it anyhow. Passion spent, you know. Yes darling, but that's why they call him Bluebeard."

---

[1] *Manchester Guardian*, Nov. 5.
[2] *Daily Mail*, Nov. 7.

"Clarice, but darling, hello! Its ages since I spoke to you. But of course I'll call Binksie. Yes I'm sure she'd love to come to dinner. No, not so hard now. No, no real brainwaves. Research isn't like that at all really. Old Bluebeard gets an occasional ripple and then Binksie goes through the files—to look up the statistics—and crystallises it out. I'll give her a call. Oh no darling not too busy at all. Just working out a scheme on how to spend £500. My money? No darling, of course not. It's hospital money. Well naturally it's important. No it's not how to make it go round, it's how to spend it all up. Well, if they don't get it all spent up by the end of the year then they lose it. Surely you remember that show *Zip Goes a Million?* Well, that gives you some idea of research. Yes darling, just some idea . . ."

* * *

What fine fellows the pioneers and research-workers are, whose names appear on the pages of our textbooks—inventors of anæsthetics, microscopes, syringes, antibiotics, and all the paraphernalia of modern medicine. How wonderful. So I mused this morning, while shaving. Suddenly I realised that ordinary life, too, is nurtured by countless friendly ghosts—inventors of brushes and combs, loofahs, towels, and soap, beds and pyjamas. It was then that I nearly cut myself with my safety razor when my face puckered the wrong way in a smile.

* * *

I drove up to the branch surgery to take my second session, and started taking my things out of the car under the interested eyes of Michael, aged 7, and Teresa, aged 5, the caretaker's children. With quiet professional pride I overheard Michael telling Teresa that I was the new doctor. She conceded one scornful glance in my direction. "That's not a doctor," she said, "that's a lady." I gave myself the benefit of the doubt and took this as a compliment—only to be dashed by her explanation: "She's got lipstick on."

* * *

Advertisement from the Bath Chronicle, Thursday, March, 20, 1777.

WANTED, for a family who have bad health, a sober, steady person, in the capacity of doctor, surgeon, apothecary, and man-midwife: He must occasionally act in the capacity of butler, and dress hair and wigs: He will be required to read prayers occasionally, and a sermon every Sunday evening. The reason of this advertisement is, that the family cannot any longer afford the expences of the physical tribe, and wish to be at a certain expence. A good salary will be given. N.B. He will have liberty to turn a penny in any branch of his profession when not wanted in the family.

* * *

My daughter, aged 8, was failing to respond, as doctors' children do, to the application of a parent's skill. Thinking to prepare her for an ordeal I suggested that we might ask a specialist to see her. She remarked with great calm and earnestness: "I am so glad, Mother; after all, you are only practising."

Letters to the Editor

DENTAL TREATMENT OF CHILDREN

SIR,—One wonders whether the argument that it is an uneconomical proposition to train dental ancillaries, because the experience of the New Zealand school dental nurses scheme has shown that a proportion of dental nurses leave the service when they marry, is to be carried to its logical conclusion. The argument applies with even greater weight to the training of women dental surgeons, since many of them also retire on marriage and most others carry on their professional work afterwards only on a part-time basis. The economic loss is substantial, since their training has been much more costly than would be that of an ancillary, and during their course of study they have monopolised facilities which could have been used to train a man who would have given the community many more years of service after qualifying as a dentist. Logically, we should expect the dental schools to be closed to women so that the greatest benefit could be derived from limited accommodation and teaching staffs, in the interest of increasing the number of dentists actually practising as distinct from an increase in the number of names on the Dental Register. Actually, the proportion of women students following the dental course increases steadily with the years and apparently no-one feels that this is an economically wasteful development. It would, of course, be a great pity if women were debarred from the dental profession, for they have an important part to play; but this retrograde step would be the logical conclusion of the argument about "wastage."

There is no valid reason why this "wastage" factor should not be reduced in importance by recruiting men as well as women for training as dental ancillaries.

Mr. Rosenstiel (Nov. 8) is surely wrong if he believes that children's dentistry can be learnt by gaining skill and experience in treating adults. No amount of experience of adult dentistry will, by itself, enable a dentist to treat satisfactorily his child patients. A serious shortcoming of dental education has been the absence from curricula of courses in children's dentistry. Not all schools have, even now, introduced such courses, and the result is that the newly qualified dentist may have little or no experience of treating children, no instruction in the different techniques involved, and little practice in gaining the confidence of small children. Most of us have had to acquire this experience after qualification, much of it simply by means of "trial and error." The dental nurse, on the other hand, would receive, at the hands of experienced practitioners, a training exclusively in the treatment of children and would thereby become something of a specialist in the techniques of fillings and extracting children's teeth. The wider experience necessary for diagnosis and treatment planning would be provided by the dental surgeon supervising the team of ancillaries, and he would also perform all the more difficult operations encountered.

I quite agree with Mr. Wookey that orthodontic work is a more interesting aspect of children's dentistry. Unfortunately we school dentists are morally obliged to devote the greater part of our time and energy to the urgent task of combating dental disease. Until we can pass on to ancillaries the less skilled routine operations, we shall be unable to make full use of our expensively acquired skill in other directions; and orthodontics, though important, must take a secondary place in our activities. Our skill and knowledge are at present largely wasted because we must spend so much of our time on work which could be equally well performed by an ancillary with a purely technical training.

SENIOR SCHOOL DENTAL OFFICER.

GRADING REVIEWS AND THE CHEST PHYSICIAN

SIR,—In 1949, in response to protests against the decisions of the original grading committees, the Ministry of Health promised that these decisions would be reviewed in two years' time; and, although mention was made of the opportunity offered for the attainment meanwhile of further qualifications, the Ministry promised that all cases would be reviewed. When the review committees were set up in 1951, however, the Ministry issued a circular which was in effect a directive emphasising higher qualifications or additional responsibilities since 1949 as the criteria for decisions. Most of the review committees acted upon this advice and refused to consider any appeal based on a claim of injustice in the original decisions. This was a contravention of the Ministry's promise.

There is still widespread dissatisfaction with the later gradings, and representations are being made. In this letter I want to draw your readers' attention to the particular case of the tuberculosis service.

Before 1948 the tuberculosis service was largely isolated from other branches of medicine. Even now, the work of an efficient chest clinic not yet within the curtilage of a hospital seldom comes to the notice of general physicians, surgeons, and gynæcologists, or even of many chest consultants serving at teaching hospitals, who have little conception of the nature or volume of the work done, the problems to be faced, and the standards attained. Only the few inefficient clinics draw attention to themselves.

The review committees, composed mainly of consultants in general medicine or surgery with only one direct representative of the whole-time tuberculosis service, had therefore little or no personal knowledge of the work of individual appellants; and they not infrequently rejected the advice of the specialist members of the committees. It is not surprising therefore that there were inequalities and injustices in the decisions arrived at both within the various regions and between them. The disparities within the regions sometimes gave rise to suspicions of prejudice but were perhaps due rather to varying degrees of knowledge of the particular clinics concerned. Between the regions, no uniform standard of judgment was possible without well-defined criteria.

There is a special case for reconsideration of the status of chest physicians in general apart from their individual claims. Most if not all of them are transferred officers, already doing consultant work for general practitioners and Government departments; and often they are of considerable seniority, well established in posts to which they were appointed in competition with others on the basis of medical and personal qualifications and experience. The majority of their posts are on the establishment as consultant posts and would be advertised as such if they resigned.

Most of these men, by reason of their age and responsibilities in whole-time posts, would find it impossible to seek further qualifications in general medicine; and in the opinion of their colleagues in the service they already fulfil the conditions laid down in the Ministry's original directives of 1949. Many of them hold the higher qualification previously required by the Ministry for senior posts in the tuberculosis service (D.P.H.). They have all acquired specialised experience in fields of work presenting greater complexity than many other branches of medicine; for example, the rehabilitation of the tuberculous which calls for a high standard of clinical judgment, and the problems associated with chronic infectious disease. Though this work is of great importance to the community, there has been a tendency to decry it as of less value than purely clinical work.

There is little chance of their obtaining consultant posts elsewhere in competition with younger men straight from training hospitals and with higher academic distinctions; nor should they be expected to give up the posts to which they have contributed many years' work in order to seek similar posts in other districts. They are therefore condemned to spend the rest of their professional careers as senior hospital medical officers—perhaps fifteen or twenty years or more—with inferior status in the eyes of their colleagues in other specialties and little heart to give of their best.

This is a non-recurring problem, particularly in the chest service, for the status of all new posts is now fixed before appointment, and new officers will not be expected to do consultant work without consultant status. The principle should be established that all S.H.M.O.s doing consultant work and/or in charge of chest units should be upgraded to consultant status if not already graded as such. There are less than 200 doctors involved: the cost would be comparatively small but the gain a satisfied service. The principle has already been accepted in the Welsh region with happy results.

If, however, this principle is not accepted for all regions, certain provisos should be insisted upon in any further review. The review committees for each specialty should consist predominantly of assessors who have first-hand knowledge of the work of the specialty: in the case of chest physicians, this means practical experience in or close association with chest clinics. Secondly, full weight should be given to the opinion of those practitioners, general and consultant, and local authorities who have direct knowledge of the work being done at the particular clinic.

London, N.1.   C. K. CULLEN.

CLIMATE AND INFECTION

SIR,—I was very interested to read in Dr. Waddy's article (Oct. 4) that he considered that drying of the respiratory mucosa might predispose to infections of the respiratory tract as well as to cerebrospinal meningitis.

I have plotted graphs of the incidence of respiratory infections occurring in Africans employed by the Magadi Soda Co. Ltd. over a period of nearly two years, and also graphs of various meteorological data. Among the latter I have included the actual evaporation-rate (in inches of water per month), which I think is a fair indication of the drying-power of inspired air. So far, peaks have occurred in the disease-incidence curve each time the evaporation-rate has fallen to an unusually low level. That is to say, when there is *less* tendency to drying of the mucosa, respiratory diseases are more common. My figures do not include cerebrospinal meningitis, for there have been no cases of this disease here in recent years.

I hope to publish the results of this investigation at the end of the two years.

Magadi, Kenya.   T. H. WHITE.

THE CORRECT SPELLING OF MEDICAL TERMS

SIR,—Spelling is a curious blend of phonetics, etymology, tradition, and nonsense; we should take care not to let the last preponderate. Dr. Napier (Nov. 1) is to be congratulated on his attack on the absurd *o* which it is customary now to insert into *fetus*. I would like to raise support for a similar attack on the *ph* with which we generally mis-spell *sulfur* and the other words derived from it.

Sulfur comes from a Latin word. Undeniably some Latin authors used the *ph* form, but there is good reason to think that this was a blunder, and most of the European languages that use the Latin root have not followed the erroneous spelling. The spelling *sulfur* was common in Britain from the 14th to 18th centuries, and this presumably explains its present day use in the U.S.A. It is in no sense an American innovation.

To adapt Dr. Napier's phrase, the *ph* crept in nearly 2000 years ago, but it is time that it too was gently eased out again.

Rothamsted Experimental Station,
Harpenden, Herts.
N. W. PIRIE.

WITHDRAWAL OF TEACHING

SIR,—I would like to underline and elaborate on Dr. Mac Keith's closing remarks last week about the need for better records of clinical conditions.

We are at the moment being asked by the Ministry of Health, through the daily press, to watch out for a visitor to this country thought to be incubating rabies. Has the Ministry taken any step to ensure that an adequate teaching record is made of this case, should it develop into frank disease? I know of only one film record of rabies existing in Britain, and that has been withdrawn from circulation. Similarly with smallpox: I have custody of one small collection of colour slides, taken recently through the beneficence of Messrs. Dalmas, of Leicester, and available on free loan to teaching centres. The only other series I know of is the excellent mass of material recorded at the turn of the century at Joyce Green Hospital—but even that is not lent out, nor is it in colour.

Again, recognised authorities have been written to, asking access to cases of anthrax, cowpox, and leprosy, amongst others: but these diseases are now so rare that when a case does turn up the physician has usually lost the letter, and begins treatment at once.

There is indeed need, as Dr. Mac Keith points out, for a ward specifically designed for recording the progress of patients under treatment. And what is more, there is a need to ensure that these records, once made, are readily available to all medical schools. The closing of the activities of the C.O.I. mobile projection units will prove to have been a severe blow to medical teaching.

London, W.1.
BRIAN STANFORD.

WHITHER MEDICINE?

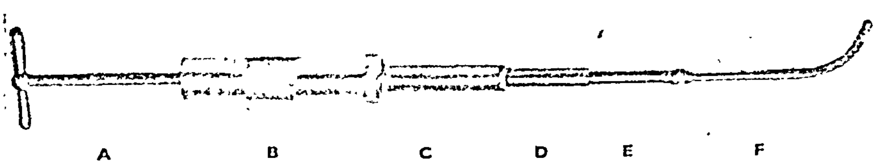
SIR,—One has always assumed that members of the profession entrusted with the task of grading their colleagues would recognise an obligation of strict confidence.

Sir Heneage Ogilvie (Oct. 25), however, sees fit in a public oration not only to express his contempt for certain individuals who, in his opinion, fail to attain consultant grade, but in two cases to give sufficient details to make the victims of his derision nearly certainly identifiable to many of their colleagues. One may well repeat with Sir Heneage "Whither Medicine?"

Horley, Surrey.
T. W. PRESTON.

MANAGEMENT OF A GASTROSTOMY AT HOME

SIR,—In general practice it is unusual to have a patient with a disease requiring gastrostomy, and a still rarer event to have the care of such a patient after operation. However, while hospital beds are scarce, the practitioner may be called on to do what he can, and to advise on home nursing.



Care of the Skin

The skin round the gastrostomy opening becomes fired by the action of escaping gastric juice, and some form of application should be used to protect the skin. The skin should be smeared for 3 in. around the gastrostomy with hydrous wool-fat, and then dusted thickly with a talc powder laced with bicarbonate of soda. A gastrostomy plug of the appropriate size should minimise leakage.

Pressure points require careful attention owing to the extreme emaciation of these patients. A time-table of bed postures should be followed so that the patient is not too long in one position.

Care of the Mouth

This is very important. Dentures are better left out, and the mouth frequently cleaned with a fragrant mouthwash, such as Glycer. Thymol Co. *B.P.C.*, or half a tablet of 'Sotol' in half a tumbler of warm water. Neglect of these precautions may lead to severe stomatitis or even to a fatal parotitis. Penicillin chewing-gum may be a help, for it stimulates the flow of saliva, and supplies a topical application of penicillin to the growth in the gullet.

Control of Pain and Infection

Pain in the chest and neck is often severe. 'Nepenthe' minims 20, diluted and passed through the gastrostomy tube, should give relief, and can be repeated when required. Constipation is often induced, and this is corrected by liquid paraffin, for a purge is not well tolerated.

Antibiotics have their place in keeping the growth clean. 'Crystopen,' a penicillin preparation containing 200,000 units per tablet, may be crushed up and given with a little fluid through the gastrostomy tube every two hours.

Diet

Most gastrostomy patients have a cancer of the gullet, so their activities are curtailed and they require only a low caloric intake, which is usually provided by nourishing fluids given by catheter through the gastrostomy. There are also those patients who have had a gastrostomy because of œsophageal damage by corrosive fluids, and they often need a fuller diet.

It would clearly be an advantage to be able to give other than liquid food, and the apparatus shown in the accompanying figure enables this to be done.

The assembled components A to E are those of an ordinary grease-gun used to lubricate motor-cars; and the end-piece F is a metal catheter about size 12 (English) with a large lateral eye. The screw ram A works in the loading barrel B, which is attached to the pressure chamber C by a screw thread. Next to C is the sleeve D into which E slides when the gun is in the feeding position. When E is in the extended position, as shown, nothing can pass.

Anything which can be made into a purée will go through this gastrostomy gun. Fine mince, boiled grated carrot, mashed potato and gravy, sieved green vegetables, and so on, will all go through it. There is no point in putting fluids through because the usual gravity method can be used.

To load the gun, detach the loading barrel and see that the screw ram is fully out. Air-bubbles in the food are dispersed by stirring with a fine rigid rod. When full, reassemble, slide E up into D, and screw the ram down into B until food appears at the eye of the catheter. Now detach B, screw A back into the empty position, top up with more food, and reassemble. The gun is now ready for use. When the point of the catheter has been greased with 'Vaseline,' it will slide easily into the gastrostomy opening. Theoretically the whole of a meal could be mixed up in one dish, but it is obviously better to serve it in courses.

Cleaning the apparatus is of the greatest importance. Detach the barrel, remove the surplus food, and screw back the ram to the empty position. The barrel is then cleaned with a bottle brush and a domestic detergent, scalded, and put on the hob or hot-plate to dry. The distal part of the apparatus is more difficult to clean, for there is a tightly packed residue of food to be forced out. This is done by fitting an inch of rubber tubing over the end of a cold-water tap so that it acts as a watertight seating when the pressure chamber C is forced tightly up against it, and the water turned on. Be sure that section E is telescoped into the sleeve D, otherwise the result will be a shower-bath. When this part is clear, boiling water can be flushed through it, provided E is in the up position.

Care of the gastrostomy patient is chiefly a matter of adequate diet, and this method is an attempt to provide a fuller diet. It has proved satisfactory in the 2 cases in which I have used it.

Longtown, Cumberland.
ROBERT RUTHERFORD.

A TECHNIQUE FOR SAVING THE VEIN

SIR,—The article by Dr. Aronson (Nov. 1) prompts me to record the following simple technique:

A transverse incision is made, the vein is exposed, and two sutures are placed round it. The ends of the proximal suture are sewn loosely through the proximal skin edge, one on each side of the vein; the distal suture is similarly sewn through the distal edge of the cut.

The vein is snicked and the cannula introduced in the normal way. The proximal suture is tied tightly over the skin, thus enclosing the vein and cannula; the second suture is tied similarly, distal to the cannula. The skin incision may now be sutured as usual.

When the transfusion is discontinued the two venous sutures are readily removed. Any bleeding will cease if the limb is elevated and firmly bandaged: it is unnecessary to repair the wall of the vein.

In cases where the vein is visible through the skin, the subsequent patency of its lumen may sometimes be evident to the eye.

FUTURE OF THE OCCUPATIONAL HEALTH SERVICES

SIR,—Many well-informed people believe that our occupational health services are inadequate. A few, in a rather nebulous and tentative way, have put forward plans for improvement. I confess I am surprised to find Dr. Lloyd Davies (Nov. 1) attacking, not a particular plan, but planning as such. *Wyld's Universal English Dictionary* defines planning as "methodical and considered arrangement of the various matters and steps necessary to carry out a project." It is difficult to see how Dr. Lloyd Davies could carry on either his own professional work or his personal life without planning. He obviously reserves the term, and his scorn, only for planning of which he disapproves. If there are planners of occupational health services who want "to hamper industry with unsatisfactory legislation" and who "assume that planning as such is a good thing"—i.e., that a bad plan is better than no plan—then they deserve criticism because their plans are bad, not because they are planners. Who are these people? I should like to read them in the original.

Before planning can begin, there must be agreement on the end in view. The collection of "accurate information, as opposed to theories and dogmatic summaries" which is what Dr. Lloyd Davies advocates, must be the next step. But by what reasoning does he equate planning with failure to do this?

West Midlands Gas Board,
Birmingham. F. H. TYRER.

SIR,—Whilst this subject is once more being debated in your columns, may I suggest a measure that could be taken at once without any increase in medical manpower or new legislation? My suggestion is that each local health authority should set up an occupational health service to cover its own staff. This would have three advantages in addition to the fact that the necessary machinery is already available. Firstly, a considerable number of employees not yet covered by any form of occupational health service would be given such a service: secondly, the local health department would gain experience of administering an occupational health service; and, thirdly, some facts and figures could be obtained in relation to small groups of office and outside workers.

I realise that a few authorities have such schemes, and that all authorities medically examine potential employees, but this latter measure is not an occupational health service. Is the lighting and heating in all our town halls adequate? Are the health and welfare regulations relating to building carried out on all local authorities' building sites? How much study has been devoted to dust suppression at refuse-disposal works? Do road workers suffer from tar-epithelioma, and what measures are advised and supervised to prevent it? Do librarians or park attendants get the most colds? Such questions indicate the scope of the problems that a local-authority occupational health service could tackle. Here, indeed, is a chance for the public-health department to do some spade work and by their results to gain the confidence of industrial medical officers.

London, W.5. M. D. WARREN.

BRITISH HOSPITALS CONTRIBUTORY SCHEMES ASSOCIATION

SIR,—In your notice last week (p. 943) of the annual conference of this association, held in Cardiff, you report me as saying:

"There was a lack of research and of health education. If people were properly informed about immunisation and other preventive measures they would be able to help themselves more and cost the National Health Service less."

I wish to point out that I did not say this or anything remotely resembling it. While painfully conscious of my limitations I at least believe myself to be incapable of uttering such platitudes.

Cambridge. FFRANGCON ROBERTS.

*** Our report was a correct abstract of an account sent to us by the association.—ED. L.

INTUSSUSCEPTION DUE TO ECTOPIC PANCREATIC TISSUE

SIR,—I should like to record an unusual case of intussusception.

A girl, aged 6½ years, the youngest of five children, was admitted to hospital at 8.30 P.M. on Sept. 4, 1952, with a history of intermittent abdominal pain and vomiting which had started suddenly about ten hours earlier. The pain was in the umbilical region and varied in intensity; when she arrived in hospital it was less severe but more frequent. The vomiting had stopped during the afternoon. Her bowels had been open normally before the onset of the pain, but not since. Micturition had been quite normal. She had had occasional attacks of abdominal pain with vomiting for the past three or four years and her mother thought these were getting more frequent; lately they had occurred at intervals of about a month. She was known to have had acetone in the urine during a number of these attacks. The latest attack had lasted longer and seemed to be more severe than any of the others. Except for pneumonia at the age of 4 she had had no serious illness.

The patient was lying quietly in bed and was not in any obvious pain. Temperature 98·8°F, pulse-rate 84 per min., respirations 22 per min. There was some fœtor oris, and the tongue was a little furred. Heart and lungs normal. The abdomen was not distended and moved well on respiration. There was some fullness in the right iliac fossa with guarding there on palpation. This revealed an elongated tumour about 2 in. (5 cm.) long with its axis parallel to the inguinal ligament; it was slightly mobile and not very tender. Nothing else abnormal was found in the abdomen or on rectal examination. The urine contained acetone and a trace of sugar.

The diagnosis appeared to be either an intussusception or an inflamed appendix surrounded by omentum.

The abdomen was opened through a lower right paramedian incision. There was some clear yellow fluid in the peritoneal cavity, and in the right iliac fossa there was an ileo-ileal intussusception about 5 in. (13 cm.) long, bent into nearly half a circle by the attachment of the mesentery. Reduction proved impossible, owing to the tightness of the proximal end: and a resection with end-to-end anastomosis was carried out, leaving about 1 ft. (30 cm.) of ileum between the anastomosis and the cæcum.

The patient's convalescence was uneventful, and she went home on the seventeenth day after operation.

Examination of the specimen showed a tumour about ½ in. (1·5 cm.) across in the wall of the intestine at the proximal end of the intussusceptum. It was about 30 in. (78 cm.) proximal to the ileocæcal valve in the position where a Meckel's diverticulum might be expected. The histological report was as follows: "The nodular lesion consists of ectopic pancreas. This is situated mainly in the submucosa, but extends into the muscularis. The overlying mucosa is hæmorrhagic and shows early ulceration. A mesenteric lymph-node shows a widely distended sinus and mild inflammation."

Pancreatic tissue is found occasionally in the duodenal region and the upper jejunum, but I can find no published record of its occurrence in the lower ileum.

I am indebted to Dr. C. C. S. Pike for the histological report.

Peace Memorial Hospital, Watford. **A. P. KITCHIN.**

A PREGNANCY TEST

SIR,—Although pregnancy tests, such as the Aschheim-Zondek and Friedmann tests, are well established, it is often difficult to obtain mice and rabbits in suitable condition in laboratories where these tests form only a small part of the routine work, such as those at military hospitals. For these laboratories a simple and reliable method, such as that described by Galli-Mainini,[1] by Frazer and Wohlzogen,[2] and by Haines,[3] would be an advantage.

In FARELF Command a test using the male frog, *Rana rugulosa*, has been in use in the physiology department of the University of Hong-Kong and at the public-health laboratories there, and by courtesy of the directors specimens have been examined for the Services. This frog, however, is not found in the wild state in Malaya. On the other hand, a toad, *Bufo melanostictus*, is found throughout South-East Asia; and though it hibernates in Hong-Kong, it is readily available all the year round in Malaya. An experiment by Dr. Audrey Driver and Dr. Hou Chien-Tsun, in the department of physiology at Hong-Kong showed that the frog was slightly more sensitive than the toad to the urine of pregnant women, but agreement was reasonable. It was decided therefore to adopt for routine use in the pathological laboratory at Singapore a test in which three toads were used and the urine concentrated by the method described by Scott.[4]

Technique

An early morning specimen is required. If it cannot be used at once it should be frozen to limit bacterial growth. It is advisable to concentrate the urine tenfold and this takes about an hour.

The following reagents are used:

(1) Bromphenol blue .. .. .. 0·4 g.
  0·05 *N*/NaOH .. .. .. 15 ml.
  Grind up to make 100 ml. with water.
(2) 20% aqueous suspension of kaolin (preferably kaolin B.D.H. washed with acid).
(3) 20% HCl.
(4) 0·1 *N*/NaOH.
(5) 10% HCl.

Take 100 ml. urine, 100 ml. water, and 1 ml. indicator in a measuring funnel. Adjust the pH to 4·0 with 20% HCl until the blue colour almost disappears. Add 10 ml. kaolin suspension. A coarse precipitate rapidly forms. Pour off supernatant liquid and transfer the deposit to a one-ounce bottle. Centrifuge, and extract the deposit with 10 ml. of 0·1 *N*/NaOH, shaking well. Centrifuge again, pour off the supernatant liquid, and adjust its reaction with 10% HCl until it is just acid to litmus.

Three male toads are then examined to make sure their urine contains no sperms. A glass pipette with rounded ends is inserted into the cloaca for ½–¾ in., and gently moved in and out until some urine is sucked up. This is then examined for sperms under the dry lens.

2 ml. of the concentrated urine is injected into the dorsal lymph-sac of the toads. Urine is collected from the animals after two and four hours, and a drop on a slide is examined for sperms.

Results

Of 93 tests made between August, 1951, and April, 1952, 76 are strictly comparable, for the technique did not vary and a follow-up was possible. The results in these cases were:

(1) 28 true positives (confirmed clinically);
(2) 34 true negatives;
(3) 14 false negatives;
(4) No false positives.

Some false negatives were not unexpected, for the tests were sometimes asked for after as little as four and a half weeks' amenorrhœa. False negatives also occurred when pregnancy was advanced and fœtal parts visible on X-ray examination. Other workers have found that the level of gonadotropins falls in these circumstances.

Toads

It was easy enough to catch toads at night either with a torch or near the street lamps where the insects gathered. They were kept in a brick enclosure, sheltered from the sun. There was 2 in. of water and some islands of bricks in the enclosure, and the toads usually hid under a collection of bricks or sat on an island. It was simpler to catch the toads as required, and to keep only a small stock of a dozen. It was then unnecessary to feed them. All toads that were positive in the tests were released far from the collecting area, but toads that were negative were used again.

All toads were examined for free sperms before being used, but no free sperms were ever found. Certain toads were found which did not react—hence the use of 3 toads for every test.

No animals died after injection of the concentrated urine, though in preliminary trials some unconcentrated urines were fatal to the toads. Scott[4] has pointed out that toxic substances are retained by the kaolin. Toads weighing 25 g. would be unaffected by 5 ml. of isotonic saline, but often killed by 5 ml. urine.

In our limited experience this test was sufficiently sensitive to be of clinical use. Moreover, it was inexpensive, it gave a result on the same day—in some positive cases within an hour and a half of receiving the sample of urine—and it never gave false positives.

Pathology Laboratory,
FARELF.

FATE OF THE FACE IN POLIOMYELITIS

SIR,—After seeing Dr. Moore's interesting report[5] on the outcome of facial paralysis in poliomyelitis, we thought that it would be of interest to follow up our cases seen in recent years.

Among 188 cases of poliomyelitis, including 72 non-paralytic, seen in the years 1947–50 there were 11 instances of facial weakness. (This excludes a further two or three cases of the severe bulbar form of the disease in which the patients died.) Of the 11 patients 10 were traced.

2 (male aged 18 years, female aged 17 years) had transient weakness which disappeared while they were in hospital.

3 (males aged 27 and 9 years, female aged 7 years) had mild weakness affecting the mouth only or the mouth and, very slightly, the eye. These recovered completely.

2 had moderately severe weakness of the mouth and the eye, though both mouth and eye still showed some movement. One patient (male aged 36 years) improved greatly for six months, then was left with slight but definite weakness of mouth and eye. The other patient (female aged 1 year 10 months) recovered completely.

2 had severe weakness of mouth and eye, with hardly any movement remaining. One of these (female aged 9 months) showed a slight flicker of the mouth, and after nine months her eyes were seen to close in sleep; but no further improvement ensued. The other (female aged 3½ years) showed little or no improvement.

1 patient (male aged 13½ years) recovered completely; but the degree of weakness was not recorded at the start.

Public Health

Family Life in Great Britain

FAMILY life in the happy self-sufficient British tradition generally accepted in this country as an almost essential ngredient in the formation of good character: its bsence or disturbance is held responsible for juvenile elinquency, the problem child, and even the severer orms of mental disorder. From the narrower sociomedical standpoint, contentment and security of the amily circle plays an important part in recovery from lness; and, at the level of health-service administration, he medical care of the sick person without a family to ssist in that care is often a grave problem.

What now constitutes a typical British family? The econd instalment of the 1951 sample Census tabulations[1] the first was reviewed in our issue of July 19) provides n answer. A novel analysis, not attempted at any revious British Census, shows the internal composition f private households—the kind of people in them nd how they were related to one another. Of the otal of 14½ million households in Great Britain in 1951, 11½ million were of the simplest type—i.e., a married ouple, or a widowed person, with or without children, r persons living alone. Nearly another million households were of this simple type except for the inclusion of parents or non-married brothers or sisters of the head of a household. The remainder, numbering under 2 million, contained more distant relatives or non-relatives (often boarders) of the head. In three-quarters of the total households a married person was the head; in a sixth the head was widowed or divorced; while the remaining "heads" were single (five-sixths of them being over 40 years). Tables are given showing the frequency of different patterns of blood relationship. The medical social worker is interested not only in blood relationship but in psychological relationships and emotional attitudes. On these, of course, a Census must be silent. Social medicine must get out into the field.

Married couples living in other people's homes are often a social problem, and occasionally a medical problem. The sample enumerated some 820,000 couples in this situation. Most of them were married children of the head of the household or of his spouse. There were also about 400,000 widowed or divorced persons living in homes of their married children. Married couples living alone are also important, for a third of them were over 60 years old.

In one sense family life is unavoidably more self-sufficient than it was: the family retainer has almost disappeared. Resident domestic servants in private households have fallen in number from 706,800 in 1931 to 178,000 in 1951 (in this comparison the figures relate to England and Wales and not Great Britain).

What about people who are not in their own homes? There were 840,000 persons in hotels, boarding-houses, and the like; 120,000 in schools and children's homes; 380,000 in civilian hospitals and nursing-homes; 220,000 in mental institutions; 67,000 in homes for permanently disabled or aged; and 500,000 in Defence establishments—altogether about 2,400,000 living outside private households. The main change since 1931 lies in the large increase in the number in Defence establishments.

How big were the families? There is of course today a higher proportion of small families and a lower proportion of large families. The fertility question at the Census was addressed to married women under 50, many of whose families were incomplete. The proportion of these in the sample who had not so far borne a child was 21·5%; with one child 30·2%, with two children 25·9%, with three children 12·0%, and with four children 5·2%. There were barely 5% with families of five or more children and less than ⅓% with ten or more children. In 1911 more than a fifth of married women under 45 had five or more children. Families in social class 1 have not fallen in size so much as those in the lower social classes.

The Census tabulations give information of the birthplaces of people. Not all the families were British by birth, and not all of them have acquired British nationality. The large influx of aliens since 1931 colours the picture. The greatest increase has been in natives of Poland, from 45,000 in 1931 to 165,000 in 1951. The German-born rose from 29,000 in 1931 to 111,000 in 1951 and the Russian-born from 39,000 to 77,000. Large increases were also recorded for natives of Austria, Hungary, and Czechoslovakia.

Estimate of Future Births

The Registrar-General's final estimate for live births in England and Wales during the December quarter is 158,000, and his provisional estimate for the March quarter, 1953, is 170,000, giving an estimated total of 328,000 babies in the six months. There were 153,995 live births registered in the December quarter of last year and 173,503 in the March quarter of this year—a total of 327,498. This year's number of live births registered in the 160 Great Towns up to Oct. 25 was 328,915 compared with 338,618 in the same period last year.

Consumption of Milk in Schools

In his report for 1951, Dr. J. B. S. Morgan, medical officer of health for Derbyshire, wonders why there has been a decline in the proportion of school-children in the county who drink the free milk issued to schools. In 1946 89·3% of children in secondary schools took milk, but by 1951 the figure was down to 64·8%. During the same time the percentage in primary schools fell from 94·8 to 87·3. In a previous report Dr. Morgan recommended that the milk be made more attractive to children by adding some suitable flavouring, but the Ministry of Education was unable to sanction expenditure for this purpose. He says in this year's report that a survey of the county's schools is being made to find out why there has been this decline, and we are indebted to him for sending us the opinions given by the heads of schools. The following were among the reasons suggested:

(1) There is more milk at home, so less is needed at school;
(2) ice-cream is a growing counter-attraction;
(3) inducing children to drink milk puts them off it;
(4) taking milk off the ration has had a psychological effect;
(5) mid-morning milk spoils the appetite for lunch;
(6) time spent drinking milk is playtime lost;
(7) children think the milk is too cold in the winter or, quite wrongly, sour in the summer;
(8) some children are forbidden to drink milk by parents' or doctor's orders;
(9) the children just do not like milk;
(10) as the milk costs nothing, it is no longer appreciated.

Parliament

Accommodation for Mental Defectives

IN the House of Commons on Nov. 5, Mr. BERNARD BRAINE pointed out that institutions in England and Wales were accommodating 49,000 defectives, while there was a waiting-list of 8000, of whom half were children. Since the introduction of antibiotics and sulphonamides the death-rate in these institutions had fallen, and as a consequence many children remained on the waiting-list for years. High-grade mental defectives, once they were stabilised, could become useful citizens, but too often they were not admitted to institutions early enough to enable anything to be done for them. Sometimes they came into institutions through the courts because they had got into serious trouble. More accommodation and staff were required, and more voluntary workers to care for defectives outside the institutions. More should be done to attract the right kind of people for this work. Insufficient elasticity was allowed to hospital management committees in the appointment and pay of their staff.

---

[1] Census, 1951, Great Britain, 1% Sample Tables. Part II. H.M. Stationery Office, 1952. £2.

Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, admitted that there was a serious shortage of accommodation, but could not agree that nothing had been done to meet the problem. On the contrary, 3066 new beds in the regional hospital board hospitals for mental defectives had been opened since the appointed day. In addition many under-staffed beds had been equipped. Despite this the waiting-list had risen from 3933 on the appointed day to 7929 at the beginning of this year. They had to face the fact that the demand was growing faster than it had been possible to open beds. They needed 15,000 new mental-deficiency beds. At the moment 2145 were out of use for lack of staff. The average percentage of hospital capital expenditure allocated to mental health had risen from 19·8 in 1950–51 to 26·1 in 1951–52, and it was expected to be 30·2 in 1952–53. For mental-deficiency treatment alone the proportion of capital expenditure allocated was 7·1 % in 1950–51 and 11·4 % in 1951–52, and it would be 10·9 % in 1952–53. There had also been an appreciable increase in nursing staff. The figures she quoted covered staff and beds in hospitals mainly used for mental defectives. In 1948 the number of full-time nurses was 5941, and this year it was 6542. The staffed beds were 48,793 in 1948, and they were now 54,025. This increase was not great enough, but it showed steady progress, and the Ministry were taking steps to see that greater accent was put on the problem by the regional boards.

One disquieting fact was the decline in the recruitment of student nurses. To meet this need the various advisory bodies who made recommendations to the Ministry of Health and the Ministry of Labour on the problem had been discussing pay and training in an endeavour to see if the training could be shortened for generally trained nurses who decided to take up mental nursing. Student mental nurses received £30 a year more at all stages than student nurses in general hospitals, and trained staff up to assistant matron and assistant chief male nurse got £20 more than the equivalent grade in the general hospitals. She believed that the recent increase agreed to by the Whitley Council for all nurses would do much to help recruitment.

Births, Marriages, and Deaths

BIRTHS

BRADFIELD.—On Nov. 4, at the Royal Hampshire County Hospital, Winchester, to Hazel (née Holloway), wife of Dr. Parker Bradfield—a daughter.

GILBEY.—On Oct. 29, at Parklands, Durban, to Joan Mary (née Hulse), wife of Dr. A. L. Gilbey—a daughter.

GIMSON.—On Nov. 4, at The Chantry, Aylesbury, to Elizabeth, wife of Dr. Peter Gimson—a son.

LEGGATT.—On Nov. 3, at St. Anne's Nursing Home, Oxford, to Elizabeth (née Newton), wife of Dr. H. D. Leggatt—a daughter.

MARTEN.—On Nov. 2, at Shearwood Road Nursing Home, Sheffield, to Margaret (née Pervical), wife of Dr. R. H. Marten, M.R.C.P.—a daughter.

MARTIN.—On Nov. 2, at Norgrove, The Bishops Avenue, N.2, to Mary (née Sowels), wife of Dr. A. J. Martin—a daughter.

PRIDAY.—On Nov. 5, at the Royal Bucks Hospital, Aylesbury, to Grace Josephine, wife of Dr. C. O. M. Priday, of Buckingham—a daughter.

ROBERTSON.—On Oct. 28, at Liverpool Maternity Hospital, to Elizabeth, wife of Dr. A. John Robertson—a daughter.

TEPPER.—On Nov. 8, at Bromley Maternity Hospital, Kent, to Rachel (née Claiman), wife of Dr. R. Tepper, M.R.C.P.—a daughter.

MARRIAGES

COOK—BALSTON.—On Oct. 28, Henry Pattullo Cook, F.R.C.S.E., lieut.-colonel I.M.S. retd, to Cecily Clare Balston, of Perth, Western Australia.

DEATHS

ANDREWS.—On Nov. 2, Maynard Campbell Andrews, M.D. Camb., aged 50.

MCKELVIE.—On Nov. 3, John Douglas McKelvie, M.D. Edin., of Blofield, Norwich.

MUNRO.—On Nov. 8, at Halton, Bucks, Sir David Munro, K.C.B., C.I.E., M.B. Edin., LL.D. St. And., F.R.C.S.E., air vice-marshal retd, of Crosshill, Wendover, aged 71.

PATERSON.—On Nov. 7, at Chatfield, Alton Road, Parkstone, Dorset, Archibald Richard Paterson, M.D. Camb., aged 81.

RIDEWOOD.—On Nov. 8, in London, Harold Edward Ridewood, M.D., M.S. Lond., F.R.C.S., of Victoria, British Columbia.

TURNER.—On Nov. 4, at Ravensnest, Hythe, Southampton, Arthur John Turner, M.B. Durh.

VERLING.—On Nov. 4, Algernon Verling, M.B. N.U.I., of Oxclose, Newmarket, co. Cork, Eire.

WOOD.—On Nov. 8, at the Queen Elizabeth Hospital, Birmingham, Helen Margaret Wood, M.B. Birm., D.A.

Notes and News

A FIRST FIVE YEARS

FIVE years can seem a long time or a short time according to what you are doing. If you are setting up a new university department the years soon pass, and in their first report the Nuffield Department of Industrial Health of the University of Durham have to record a packed and strenuous quinquennium. In many ways the new department had a good start. They were backed by a generous grant of £40,000 to be spread over ten years, from the Nuffield Foundation. Office and laboratory accommodation was provided for them in King's College, Newcastle upon Tyne, where other interested departments, such as chemistry, physics, and engineering, were close and helpful neighbours. Across the road a large teaching hospital offered clinical facilities, and a little further afield the varied industries of the district offered material for research.

The department's first task was to define industrial health, which they did as "the reciprocal relation between health, home, and job," and it is against the background of this definition that their programme of research and teaching has been planned. One of their difficulties was to strike a balance between the conflicting claims of research, teaching, and preventive medicine. They early realised that their programme "must be leavened by practical idealism and tempered by the realisation that work can only be done with the materials at hand." Accordingly they accepted the problems thrown up by the local industries and chose for their first research project studies of coalminers' nystagmus and pneumoconiosis, and a statistical survey of accidents and absence from work in shipyards. The growing demand that machines should be made to fit the man rather than that man should be expected to do the best he can with the machine has led the department to study human response to variations in design of machinery, and they have built a piece of apparatus to assess the speed and accuracy of response to different designs of visual indicators. The acid erosion of the teeth of workers in a local chemical factory has also been investigated.

As teachers the department have been responsible for the instruction of medical and engineering students, as well as of almoners. They have also held postgraduate lectures for candidates for the D.P.H. and for engineers studying for higher qualifications. Two outpatient clinics are held each week at the Royal Victoria Infirmary, and 6 beds have been allotted to the department for inpatient work. In all 1127 outpatients and 271 inpatients have been seen. An outpatient clinic has also lately been opened at Dryburn Hospital, Durham. The department also runs an advisory service which has answered industrial and medical inquirers living as far away as Dundee and Somerset.

The load of these busy five years has been carried by a team of twelve of which Prof. R. C. Browne, the director, and his two assistants are the medical members.

MANUFACTURE OF CORTISONE

CORTISONE acetate is now being produced in this country by Bayer Products Ltd., who delivered the first consignment to the Ministry of Health last month. Details of the process have not been disclosed, but the starting-point is a steroid derived from ox-bile. An ox-bile synthesis is also used in the manufacture of cortisone in the U.S.A. The Bayer process has been evolved at the Sterling-Winthrop Research Institute in New York and at the Bayer laboratories in this country. Production will depend largely on imported raw material, for there are not enough cattle in this country to provide all the bile needed. By July next year, however, home production should exceed the present rate of consumption, and some of the surplus may be exported. The drug will be issued in 25 mg. tablets for oral administration and as a crystalline preparation. The cost will be about £4 per g. All supplies will continue to be distributed by the Ministry.

Royal Society of Edinburgh

A David Anderson-Berry medal and prize (about £100) will be awarded during 1953 for work on the therapeutic effect of X rays on human diseases. Applications should reach the general secretary of the society, 22, George Street, Edinburgh 2, not later than March 31, 1953.

---

1. Browne, R. C. *Lancet*, 1951, i, 721.

University of Oxford

On Nov. 1 the degree of D.M. was conferred on John Badenoch and A. I. Spriggs.

Royal College of Physicians of Edinburgh

At a meeting of this college held on Nov. 4 with Dr. W. A. Alexander, the president, in the chair, the following were elected to the fellowship:

T. F. Corkill, James Lawson, John Kinnear, J. M. Alston, A. W. E. Soysa, Freddy Himmelweit, Thomas Scott, J. J. J. Giraldi, D. R. MacCalman, R. W. D. Turner, W. I. Card.

The following were elected to the membership:

A. D. T. Govan, G. W. A. Dick, J. C. Bowe, K. B. Kapur, J. Harper, D. C. Campbell, J. S. Sodhy, T. F. McCarthy, M. A. Khan, Sheenah J. M. Russell, M. G. E. Hanno, H. Sadik, B. R. Billis, A. F. Fahmy, B. L. Agarwal, E. J. D. Nariman, R. M. Kapadia, O. T. Khoo, W. J. Mitus, L. Mirabel, Mariella Fischer-Williams, I. R. Yudaken, B. A. Akhtar, B. Seltzer, S. C. Shah, S. A. Singh, H. J. H. Hiddlestone, A. D. McInnes, J. H. Greig, H. Stein, A. W. M. Smith.

Scottish Conjoint Board

At recent examinations for licentiateship of the Royal Colleges of Physicians and Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow, the following were successful:

H. E. O. Adefope, Caroline D. Bell, I. K. Bond, Mary R. Cardwell, Stella M. Conway, R. M. Gabriel, Joan Gilbert, Chunilal Parbhoo Hargovan, E. A. Heywood, E. P. Jones, Anthony Yawovi Kpeglo, Heather J. Lopert, P. A. P. Mackenzie, R. W. Noblett, J. W. Parsons, James Peacock, E. S. O. Pratt, William Ritchie, Patricia J. A. Stewart, Ahmed El-Sayed Ahmed Touba, J. L. Tuton.

Royal Faculty of Physicians and Surgeons of Glasgow

The following have been elected office-bearers for the coming year:

President, Mr. Andrew Allison; visitor, Dr. Stanley G. Graham; hon. treasurer, Mr. Matthew White; hon. librarian, Dr. Archibald L. Goodall; representative on the General Medical Council, Mr. Andrew Allison; other members of council, Mr. Walter W. Galbraith (immediate past-president), Dr. D. F. Cappell, Dr. Alexander A. Charteris, Dr. Leslie J. Davis, Mr. W. Ian Gordon, Mr. A. D. Telford Govan, Mr. C. F. W. Illingworth, Mr. J. A. W. McCluskie, Mr. W. Arthur Mackey, Dr. Thomas Semple, and Mr. J. Forbes Webster.

Physiology of Respiration

Prof. H. Hartridge, F.R.S., will deliver a lecture on this subject on Nov. 17, 18, 19, and 20, at 5.30 P.M., at Gresham College, Basinghall Street, London, E.C.2.

Postgraduate Course in Radiology

The Faculty of Radiologists is holding postgraduate courses in diagnostic radiology and in radiotherapy at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, on Saturday afternoon and Sunday morning, Nov. 22 and 23.

London Hospital

Liddle Triennial Prize (£120).—The subject chosen for the next award of this prize is the Effect of Hormones on the Reaction of the Tissues to Injury. Essays must be delivered at the hospital not later than 4 P.M. on July 31, 1955.

Unestablished Practitioners Group

A general meeting of this group, which is an organisation for the newly qualified assistant and small-list practitioner will be held at the Hotel Russell, Russell Square, London, W.C.1, on Thursday, Dec. 4, at 8 P.M. All members of the profession are invited to attend.

Australasian Faculty of Anæsthetists

A Faculty of Anæsthetists has been set up within the Royal Australasian College of Surgeons. Till the new faculty has an opportunity of formally electing a board, Sir Victor Hurley, Mr. Henry Searby, Dr. H. J. Daly, Dr. J. Ellis Gillespie, Dr. S. V. Marshall, Dr. D. G. Renton, Dr. L. G. Travers, and Dr. G. R. Troup have been authorised to act on behalf of the faculty under the chairmanship of Dr. Renton, the acting dean. With the general approval of the Australian Society of Anæsthetists, 40 foundation fellows and 62 foundation members have been invited to join. In future applications for membership will be received from anæsthetists with appropriate qualifications, and recommendations will be made to the college council for admission to membership of those approved by the board of the faculty. The board may also submit a limited number of names annually to the college council for election to fellowship of the faculty. The secretary of the faculty is Mr. H. G. Wheeler, Royal Australasian College of Surgeons, Spring Street, Melbourne, C.1.

West Midlands Physicians Association

Dr. J. H. Sheldon has been elected president for the coming year in succession to Prof. T. L. Hardy.

Royal Society

The Buchanan medal has been awarded to Sir Rickard Christophers, F.R.S., for his research on malaria and on the anopheles mosquitoes which transmit the disease.

Metropolitan Branch of the B.M.A.

The centenary celebrations of this branch next year will include a ball in aid of medical charities which is to be held at B.M.A. House, Tavistock Square, London, W.C.1, on Thursday, Jan. 8 (tickets 2 guineas each).

Nutrition Society

This society is holding a conference at the Department of Biochemistry of the University of Sheffield, at 10.15 A.M. on Saturday, Dec. 20, on the Rôle of Vitamins in Metabolic Processes. Prof. H. A. Krebs, F.R.S., will be in the chair, and the speakers will include: Prof. C. P. H. Dam, Mr. L. J. Harris, D.SC., Mr. D. E. Hughes, Mr. T. Moore, D.SC., Mr. J. W. G. Porter, PH.D., and Dr. H. M. Sinclair. Further particulars may be had from Mr. R. J. L. Allen, Monkhouse & Glasscock Ltd., Snows Fields, London, S.E.1.

International Hospital Congress

The eighth International Hospital Congress is to be held in Church House, Westminster, from May 25 to 30, under the chairmanship of Dr. René Sand, emeritus professor of social medicine at the University of Brussels and president of the International Hospital Federation. The central theme of the congress will be Preventive Medicine as a Major Function of the Hospital, and its Implications. Further particulars may be had from Captain J. E. Stone, hon. secretary and treasurer of the federation, 10, Old Jewry, London, E.C.2.

Trials of Influenza Vaccine

The Medical Research Council, in conjunction with the Ministry of Health, is to organise trials of influenza vaccine this winter. About 15,000 volunteers—including a large number from industry, and others from among hospital nursing staffs, university students, and similar groups—will take part. The trials are due to start early next month. Two vaccines will be used: one selected on the experience of last winter's pilot trials, and the other similar to those which have been available for some years. Both are being produced in this country.

Rural Science Education

The Institute of Rural Life at Home and Overseas, in coöperation with the Association of Agriculture and the Institute of Education, University of London, have arranged two meetings on Food Science at Home and Overseas, to be held at the Institute of Education, Malet Street, W.C.1, on Saturdays, Nov. 22 and 29. Further particulars may be had from the secretary of the Institute of Rural Life, 84, Eccleston Square, S.W.1.

Princess Tsahai Memorial Hospital

Brigadier G. S. Parkinson, former dean of the London School of Hygiene and Tropical Medicine, will preside at a reception on behalf of this hospital to be held at the Belgian Institute, 6, Belgrave Square, London, S.W.1, from 3 to 6 P.M. on Wednesday, Dec. 3. The council of the hospital wishes to raise further funds to complete payment for equipment already installed in the hospital at Addis Ababa and to make other essential purchases. Donations should be sent to Lord Horder, the hon. treasurer, c/o Messrs. Gould & Prideaux, 88, Bishopsgate, E.C.2.

Register of National Medical Conferences

As a result of requests from medical societies, the British Medical Association has established a central register of national medical conferences. By means of this register, before finally fixing the date of a meeting a society can make certain that no other meeting on the same, or an allied, subject is being held in this country at the same time. The register will be complementary to the similar work in the international field by the Council of International Organisations of Medical Sciences, with which liaison will be maintained. Further details can be obtained from the public relations officer, B.M.A. House, Tavistock Square, London, W.C.1.

Society of Chemical Industry

At a meeting of the crop protection panel of the agriculture group of this society, to be held at the rooms of the Chemical Society, Burlington House, Piccadilly, London, W.1, on Monday, Dec. 15, at 5.30 P.M., Mr. H. E. Harbour of the Cooper Technical Bureau will deliver a lecture on the Chemical Control of Animal Parasites.

Race Problems in the Light of Modern Science

The British Social Biology Council are holding a conference on this subject on Saturday, Dec. 6, at University College, London, W.C.1. The speakers will include Dr. A. F. Mourant and Mr. Kenneth L. Little, PH.D. Tickets (*7s. 6d.*) can be had from the secretary of the council, Tavistock House South, Tavistock Square, W.C.1.

Ophthalmological Society of Egypt

This society will celebrate its 50th anniversary during its annual general meeting, which is to be held in Cairo in February. The speakers will include: Dr. D. C. Cogan (Boston), Prof. Karl Lindner (Vienna), Mr. Keith Lyle (London), Prof. Louis Paufique (Lyons), Prof. R. Thiel (Frankfort), and Prof. P. Thygeson (California). Further information may be had from Dr. Mohammad Khalil, the hon. secretary, 15A, Sherif Pasha Street, Cairo.

EMERGENCY BED SERVICE.—In the week ended last Monday, applications for general acute cases numbered 947. The proportion admitted was 92·29%.

From the beginning of next year a new journal is to be published under the titl[illegible] [illegible]matica. *Ortho-pædagogica.* [illegible] [illegible]fice should be addressed to B[illegible] [illegible] Clinic, Leyden-Oegstgeest, H[illegible] [illegible] by S. Karger, of Basle, Switzerland.

Diary of the Week

NOV. 16 TO 22

Monday, 17th

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. *Mr. S. L. Hignett, B.SC.: Prenatal Mortality in Domestic Animals.*

HUNTERIAN SOCIETY
8.30 P.M. (Apothecaries' Hall, Black Friars Lane, E.C.4.) Dr. Ffrangcon Roberts, Mr. Ritchie Calder, Mr. James Griffiths, M.P., Prof. L. P. Garrod: That the Continued Advance in Medicine will Produce more Problems than it Solves.

Tuesday, 18th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Prof. F. J. W. Roughton, F.R.S.: Kinetics of Rapid Chemical and Biological Reactions.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. *Section of Pathology.* Dr. W. N. Goldsmith, Dr. W. Feldberg, F.R.S., Prof. J. R. Marrack, Dr. J. F. Ackroyd, Dr. R. Lovell: Basis of Allergic Reactions.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. D. O'Neill: Psychiatric Aspect of Skin Disorders.

WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck Street, W.1
5.30 P.M. Dr. T. Rowland Hill: Neurological demonstration.

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mr. Kenneth Hutton, D.PHIL.: Intelligence Quotients and Differential Fertility—Some Observations from Winchester College.

SOUTH WEST LONDON MEDICAL SOCIETY
8.30 P.M. (Bolingbroke Hospital, S.W.11.) Dr. R. Ewing Rogers Coronary Disease.

[illegible] [illegible]L SOCIETY
[illegible] [illegible] of Manchester.) Prof. H. E. Sigerist (Yale): [illegible] [illegible]f Hippocrates.

Wednesday, 19th

ROYAL SOCIETY OF MEDICINE
8.15 P.M. *Section of General Practice.* Dr. M. Mautner: Peptic Ulceration.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5.30 P.M. Mr. L. H. Savin: Surgery of the Ocular Muscles.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. Wilfrid Sheldon: Children in War-time.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. I. W. Whimster: Reticuloses.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
2 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Mr. John Howkins: Surgical Treatment of Carcinoma of the Cervix.
3 P.M. Dr. L. Walter: Modern Trends in Radiotherapy of Pelvic Disorders.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Mr. J. Sandrey: Urological Emergencies in General Practice.

Thursday, 20th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. Prof. R. H. S. Thompson: Cholinesterases and Anti-cholinesterases.

ROYAL EYE HOSPITAL
5.30 P.M. Miss J. M. Dollar: Differential Diagnosis of Diplopia.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, S.W.1
5 P.M. Dr. Denis Williams: Neurological lecture-demonstration.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, W.1
8 P.M. Dr. D. A. G. Galton, Dr. E. M. Ledlie: Chronic Myeloid Leukæmia.

CHARTER[illegible] [illegible]NIC, 54, Weymouth Street, W.1
5 P.M. [illegible]: Simplicity and Profundity of [illegible] [illegible]cott lecture.)

RESEARCH DEFENCE SOCIETY
5.30 P.M. (University College, Gower Street, W.C.1.) Sir Howard Florey, F.R.S.: Advance of Chemotherapy by Animal Experiment. (Paget lecture.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE
7.30 P.M. (Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, 3.) Laboratory meeting.

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. D. N. Nicholson: Congenital Infantile Hypertrophic Pyloric Stenosis.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8.30 P.M. *Joint Meeting with Royal Medico-Chirurgical Society of Glasgow.* (242, St. Vincent Street, Glasgow, C.2.) Mr. John Gillingham, Dr. J. Romanes Davidson, Dr. R. A. Shanks: Epilepsies.

UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Dr. W. N. Pickles: Epidemiology in Country Practice.

Friday, 21st

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE
5.30 P.M. Prof. J. Gough: Pneumoconiosis the World Over.

ROYAL SOCIETY OF MEDICINE
4.30 P.M. *Section of Epidemiology and Preventive Medicine.* Dr. Tom Anderson, Dr. Joyce Landsman, Dr. R. L. Mendez, Dr. M. Liker: Respiratory Infections.
8.15 P.M. *Section of Radiology.* Mr. G. W. Blomfield: Experience with Two Million Volt X-ray therapy, and a Preliminary Assessment of Clinical Results. Dr. J. S. Mitchell, F.R.S.: Experience with the 30 MeV Synchrotron as a Radiotherapeutic Instrument.

ROYAL EYE HOSPITAL
4.30 P.M. Mr. A. J. Cameron: Medical Ophthalmology.

FACULTY OF RADIOLOGISTS
4 P.M. *Therapy Section.* (Royal College of Surgeons, Lincoln's Inn Fields, W.C.2.) Dr. D. M. T. Cones: Use of Co^{60} in Treatment of Carcinoma of Bladder. Dr. John D. [illegible] in Diagnosis and Treatment of [illegible] during the Use of P^{32}. Dr. Simon [illegible] of Gliomata with 24 MeV X rays.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. F. R. Bettley: Atopy.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W.C.1

Appointments

BLACK, WALLACE, M.B. Lond., F.R.C.S.: asst. surgeon (consultant),
Royal National Throat, Nose, and Ear Hospital, London.
BLAKE, D. H., M.B. Birm.: asst. chest physician, Leicester area.
LEAMING, H. L., M.R.C.S., D.A.: consultant anæsthetist, hospitals
in the Leicester area.
MACKIE, JOAN, M.B. Edin., M.R.C.O.G.: asst. obstetrician and
gynæcologist (consultant), Bruntsfield and Elsie Inglis hospitals.
MARTIN, K. W., M.S. Lond., F.R.C.S.: resident asst. surgeon,
St. Thomas's Hospital, London.

British Railways (London Midland Region):

RUTHERFORD, A. K. D., B.A., M.B. Dubl.: asst. M.O.
WADDELL, D. L., M.B. Glasg.: asst. M.O.
WILLIAMS, P. B., M.B. Aberd.: asst. M.O.

South Western Regional Hospital Board:

CROSS, E. G. W., M.R.C.S.: senior psychiatric registrar, Bristol mental hospitals.
HARRISON, G. E., M.B. Leeds, A.R.I.C.: deputy medical superintendent, Tehidy Chest Hospital, Camborne.
PRUS, STANISLAW, M.D. Lwow: asst. psychiatrist, St. Lawrence's Hospital, Bodmin.
RICHARDSON, R. E., M.R.C.S.: medical registrar, St. Martin's Hospital, Bath.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

LIPOMAS

Sir CECIL WAKELEY
Bt., K.B.E., C.B., LL.D., F.R.C.S.
SENIOR SURGEON, KING'S COLLEGE HOSPITAL AND BELGRAVE HOSPITAL FOR CHILDREN; SURGEON TO THE ROYAL MASONIC HOSPITAL; CONSULTING SURGEON TO THE ROYAL NAVY

PHILIP SOMERVILLE
M.A., M.B. Camb., F.R.C.S.
SURGICAL FIRST ASSISTANT, KING'S COLLEGE HOSPITAL, LONDON

THE lipoma is one of the commonest forms of neoplasm, but its incidence is difficult to ascertain, because published series refer to excised specimens received by the pathologist. These are usually a selected group removed from patients who presented for a wide variety of reasons and they take no account of patients who have not sought advice. Adair et al. (1932), reviewing 134 simple lipomas, recorded an incidence of 4–5% of their collected cases of benign tumour.

Although lipomas, especially if superficial, may seem a relatively simple problem, there are still fundamental points about them which remain uncertain—for instance, their origin, their position within the metabolic processes of the body, and their relation to other forms of local and general fat hypertrophy.

ORIGIN OF ADIPOSE TISSUE AND LIPOMA

Adipose tissue has not been studied to the same extent as other tissues. The most comprehensive review in recent times is that of Wells (1940). Briefly, the earliest view held was that adipose tissue was simply connective tissue loaded with fat. According to Wells this view remained unchallenged until Toldt, between 1870 and 1888, contended that adipose tissue was a specific tissue derived from specialised areas or organs and characterised by the formation of highly vascular lobular structures in which a special type of cell exists with the function of storing and giving up fat in accordance with supply and demand. Primitive fat-cells first take up fat in the form of fine droplets; as these enlarge, the cell takes on a mulberry or moruloid appearance, and only with an extreme degree of fat-deposit are large fat-spaces formed, the nucleus remaining central until pushed to one side.

In 1926 Wassermann and his associates placed the origin of adipose tissue on a firmer basis by showing its relation to undifferentiated mesenchymal cells. This relates the formation of adipose tissue and lymph-nodes to the same embryonic elements—i.e., the capillaries and reticulum cells of the adventitia. Supporting this is the observation of the relationship of fat and lymphoid tissue in lymph-glands and thymus, and the occasional occurrence of extramedullary hæmopoiesis in adipose tissues. In this way pre-adipose tissue is created which on maturity forms adult fat.

A great deal of investigation has been carried out on so-called glandular adipose tissue—i.e., fat composed of cells of moruloid appearance, similar to primitive fat-cells. It is not confined to embryonic life but is found in a variety of places—e.g., the adipose tissues of animals such as the hedgehog and dormouse in which it constitutes the hibernating gland. It is found also in parts of the human body, mainly in fœtal life, particularly the subcutaneous tissues of the cervicodorsal and interscapular regions as well as in the perirenal tissues of infants. These areas have been studied by Hatai (1902), Bonnot (1908), and Shattock (1909). Bonnot made a detailed study of adult and embryonic tissues and traced the origin of the glandular fat from the region of the primitive jugular vein. In man the interscapular gland is a light-brown, lobulated, and irregular vascular mass situated on the shoulder and side of the neck between the superior borders of the scapula and clavicle.

According to Wells the earliest stages of lipoma formation were studied by Borst and Bender, who found evidence for the formation of lipomas from pre-adipose tissue in the same manner as normal adult fat. It seems improbable that mature adult fat-cells can be the origin of lipomas, but whether they arise from the primitive undifferentiated perivascular mesenchymal cells or from primitive fat-cells seems uncertain. Ewing (1940) postulated a local tissue predisposition of congenital origin. Examination of lipomas shows that they are composed exclusively of normal adult fat similar to subcutaneous tissue, but in a few of them groups of primitive cells may be found. Mallory (1929) described a subcutaneous lipoma with cells similar to those seen in glandular adipose tissue; and Van Meurs (1946) described an axillary lipoma in a child which over a period of time recurred and was removed on five occasions, showing progressively greater differentiation towards a common lipoma and adult fat.

The occurrence of fatty tumours in sites where fat does not normally exist—e.g., the brain, the kidney, and the periosteum—has been ascribed to misplacement of true or pre-adipose tissue. Ehni and Love (1945), on the other hand, in their review of intraspinal lipomas ascribed their origin to a failure of normal control over the formation of fat from normally present perivascular mesenchymal cells in the pia. These cells are capable of forming fat.

The commonest sites for lipomas are the subcutaneous tissues of the neck, back, and shoulder. It is in these very regions that glandular adipose tissue in the human has been predominantly found.

In addition to the embryonic theory described above, both trauma and heredity have been suggested as factors in ætiology. Trauma does not warrant further inquiry, since it is mentioned but infrequently in the clinical history of patients: but published examples of heredity are not difficult to find, running in a few instances through more than two generations. In the present series a female, aged 35, with multiple lipomas on the arms, gave a family history of lipoma in mother and grandfather.

The relation between lipoma and nerves has often been noted, but the significance is undecided. The relationship is suggested by some tumours which are symmetrically distributed and a few which have followed a spinal injury. More definite relationship is shown by a minority of tumours which are painful, resembling the fat-hypertrophy of Dercum's disease. Adair et al. (1932) went so far as to suggest that multiple lipomas might be neurolipomas. They described the multiple type as being firmer in texture and not usually adherent to the skin. They drew a clinical analogy between multiple lipomas and multiple neurofibromatosis, both being multicentric, often symmetrical, and with a similar distribution. The two diseases are known to coexist in the same patient, and both may be associated with skin pigmentation and melanomas. The clinical resemblance may be strikingly similar.

The relation of the fat contained in a lipoma to that of the body metabolism has long been a matter of great interest, but the solution is still unknown. Wells (1912) concluded that there was no detectable chemical difference from normal fat. There appears to be no anatomical reason for the apparent isolation so well marked in the paradoxical condition of a growing fatty tumour, such as liposarcoma, and the adjacent wasting body. Wells puts forward the ingenious idea that the processes of laying down and giving up fat depend on cell differentiation and are not merely reversible physical or chemical processes.

Society of Chemical Industry

At a meeting of the crop protection panel of the agriculture group of this society, to be held at the rooms of the Chemical Society, Burlington House, Piccadilly, London, W.1, on Monday, Dec. 15, at 5.30 P.M., Mr. H. E. Harbour of the Cooper Technical Bureau will deliver a lecture on the Chemical Control of Animal Parasites.

Race Problems in the Light of Modern Science

The British Social Biology Council are holding a conference on this subject on Saturday, Dec. 6, at University College, London, W.C.1. The speakers will include Dr. A. F. Mourant and Mr. Kenneth L. Little, PH.D. Tickets (*7s. 6d.*) can be had from the secretary of the council, Tavistock House South, Tavistock Square, W.C.1.

Ophthalmological Society of Egypt

This society will celebrate its 50th anniversary during its annual general meeting, which is to be held in Cairo in February. The speakers will include: Dr. D. C. Cogan (Boston), Prof. Karl Lindner (Vienna), Mr. Keith Lyle (London), Prof. Louis Paufique (Lyons), Prof. R. Thiel (Frankfort), and Prof. P. Thygeson (California). Further information may be had from Dr. Mohammad Khalil, the hon. secretary, 15A, Sherif Pasha Street, Cairo.

EMERGENCY BED SERVICE.—In the week ended last Monday, applications for general acute cases numbered 947. The proportion admitted was 92·29%.

From the beginning of next year a new journal is to be published under the titl [illegible] *Ortho- pædagogica.* [illegible] be addressed to B [illegible] : Jen- Oegstgeest, H [illegible] ublished by S. Karger, of Basle, Switzerland.

Diary of the Week

NOV. 16 TO 22

Monday, 17th

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Mr. S. L. Hignett, B.SC.: Prenatal Mortality in Domestic Animals.

HUNTERIAN SOCIETY
8.30 P.M. (Apothecaries' Hall, Black Friars Lane, E.C.4.) Dr. Ffrangcon Roberts, Mr. Ritchie Calder, Mr. James Griffiths, M.P., Prof. L. P. Garrod: That the Continued Advance in Medicine will Produce more Problems than it Solves.

Tuesday, 18th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Prof. F. J. W. Roughton, F.R.S.: Kinetics of Rapid Chemical and Biological Reactions.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. *Section of Pathology.* Dr. W. N. Goldsmith, Dr. W. Feldberg, F.R.S., Prof. J. R. Marrack, Dr. J. F. Ackroyd, Dr. R. Lovell: Basis of Allergic Reactions.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. D. O'Neill: Psychiatric Aspect of Skin Disorders.

WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck Street, W.1
5.30 P.M. Dr. T. Rowland Hill: Neurological demonstration.

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mr. Kenneth Hutton, D.PHIL.: Intelligence Quotients and Differential Fertility—Some Observations from Winchester College.

SOUTH WEST LONDON MEDICAL SOCIETY
8.30 P.M. (Bolingbroke Hospital, S.W.11.) Dr. R. Ewing Rogers Coronary Disease.

MANCHESTER MEDICAL SOCIETY
4 P.M. (University of Manchester.) Prof. H. E. Sigerist (Yale): The World of Hippocrates.

Wednesday, 19th

ROYAL SOCIETY OF MEDICINE
8.15 P.M. *Section of General Practice.* Dr. M. Mautner: Peptic Ulceration.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5.30 P.M. Mr. L. H. Savin: Surgery of the Ocular Muscles.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. Wilfrid Sheldon: Children in War-time.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. I. W. Whimster: Reticuloses.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
2 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Mr. John Howkins: Surgical Treatment of Carcinoma of the Cervix.
3 P.M. Dr. L. Walter: Modern Trends in Radiotherapy of Pelvic Disorders.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Mr. J. Sandrey: Urological Emergencies in General Practice.

Thursday, 20th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. Prof. R. H. S. Thompson: Cholinesterases a Anti-cholinesterases.

ROYAL EYE HOSPITAL
5.30 P.M. Miss J. M. Dollar: Differential Diagnosis of Dipl

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, S.W.1
5 P.M. Dr. Denis Williams: Neurological lecture-demonstratio

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, W.1
8 P.M. Dr. D. A. G. Galton, Dr. E. M. Leddie: Chronic Myel Leukæmia.

CHARTER[illegible] 54, Weymouth Street, W.1
5 P.M. [illegible] implicity and Profundity o [illegible] lecture.)

RESEARCH DEFENCE SOCIETY
5.30 P.M. (University College, Gower Street, W.C.1.) Sir Howa Florey, F.R.S.: Advance of Chemotherapy by Anim Experiment. (Paget lecture.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE
7.30 P.M. (Liverpool School of Tropical Medicine, Pembro Place, Liverpool, 3.) Laboratory meeting.

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh Dr. D. N. Nicholson: Congenital Infantile Hypertrop Pyloric Stenosis.

MEDICO-CHIRURGICAL SOCIETY O[illegible]
8.30 P.M. *Joint Meeting with* [illegible] *Society o Glasgow.* (242, St. Vi [illegible] C.2.) Mr. John Gillingham, Dr. J. Romanes Davidson, Dr. R. A. Shanks: Epilepsies.

LIPOMAS

Sir CECIL WAKELEY
Bt., K.B.E., C.B., LL.D., P.R.C.S.
SENIOR SURGEON, KING'S COLLEGE HOSPITAL AND BELGRAVE HOSPITAL FOR CHILDREN; SURGEON TO THE ROYAL MASONIC HOSPITAL; CONSULTING SURGEON TO THE ROYAL NAVY

PHILIP SOMERVILLE
M.A., M.B. Camb., F.R.C.S.
SURGICAL FIRST ASSISTANT, KING'S COLLEGE HOSPITAL, LONDON

THE lipoma is one of the commonest forms of neoplasm, but its incidence is difficult to ascertain, because published series refer to excised specimens received by the pathologist. These are usually a selected group removed from patients who presented for a wide variety of reasons and they take no account of patients who have not sought advice. Adair et al. (1932), reviewing 134 simple lipomas, recorded an incidence of 4–5% of their collected cases of benign tumour.

Although lipomas, especially if superficial, may seem a relatively simple problem, there are still fundamental points about them which remain uncertain—for instance, their origin, their position within the metabolic processes of the body, and their relation to other forms of local and general fat hypertrophy.

ORIGIN OF ADIPOSE TISSUE AND LIPOMA

Adipose tissue has not been studied to the same extent as other tissues. The most comprehensive review in recent times is that of Wells (1940). Briefly, the earliest view held was that adipose tissue was simply connective tissue loaded with fat. According to Wells this view remained unchallenged until Toldt, between 1870 and 1888, contended that adipose tissue was a specific tissue derived from specialised areas or organs and characterised by the formation of highly vascular lobular structures in which a special type of cell exists with the function of storing and giving up fat in accordance with supply and demand. Primitive fat-cells first take up fat in the form of fine droplets; as these enlarge, the cell takes on a mulberry or moruloid appearance, and only with an extreme degree of fat-deposit are large fat-spaces formed, the nucleus remaining central until pushed to one side.

In 1926 Wassermann and his associates placed the origin of adipose tissue on a firmer basis by showing its relation to undifferentiated mesenchymal cells. This relates the formation of adipose tissue and lymph-nodes to the same embryonic elements—i.e., the capillaries and reticulum cells of the adventitia. Supporting this is the observation of the relationship of fat and lymphoid tissue in lymph-glands and thymus, and the occasional occurrence of extramedullary hæmopoiesis in adipose tissues. In this way pre-adipose tissue is created which on maturity forms adult fat.

A great deal of investigation has been carried out on so-called glandular adipose tissue—i.e., fat composed of cells of moruloid appearance, similar to primitive fat-cells. It is not confined to embryonic life but is found in a variety of places—e.g., the adipose tissues of animals such as the hedgehog and dormouse in which it constitutes the hibernating gland. It is found also in parts of the human body, mainly in fœtal life, particularly the subcutaneous tissues of the cervicodorsal and interscapular regions as well as in the perirenal tissues of infants. These areas have been studied by Hatai (1902), Bonnot (1908), and Shattock (1909). Bonnot made a detailed study of adult and embryonic tissues and traced the origin of the glandular fat from the region of the primitive jugular vein. In man the interscapular gland is a light-brown, lobulated, and irregular vascular mass situated on the shoulder and side of the neck between the superior borders of the scapula and clavicle.

According to Wells the earliest stages of lipoma formation were studied by Borst and Bender, who found evidence for the formation of lipomas from pre-adipose tissue in the same manner as normal adult fat. It seems improbable that mature adult fat-cells can be the origin of lipomas, but whether they arise from the primitive undifferentiated perivascular mesenchymal cells or from primitive fat-cells seems uncertain. Ewing (1940) postulated a local tissue predisposition of congenital origin. Examination of lipomas shows that they are composed exclusively of normal adult fat similar to subcutaneous tissue, but in a few of them groups of primitive cells may be found. Mallory (1929) described a subcutaneous lipoma with cells similar to those seen in glandular adipose tissue; and Van Meurs (1946) described an axillary lipoma in a child which over a period of time recurred and was removed on five occasions, showing progressively greater differentiation towards a common lipoma and adult fat.

The occurrence of fatty tumours in sites where fat does not normally exist—e.g., the brain, the kidney, and the periosteum—has been ascribed to misplacement of true or pre-adipose tissue. Ehni and Love (1945), on the other hand, in their review of intraspinal lipomas ascribed their origin to a failure of normal control over the formation of fat from normally present perivascular mesenchymal cells in the pia. These cells are capable of forming fat.

The commonest sites for lipomas are the subcutaneous tissues of the neck, back, and shoulder. It is in these very regions that glandular adipose tissue in the human has been predominantly found.

In addition to the embryonic theory described above, both trauma and heredity have been suggested as factors in ætiology. Trauma does not warrant further inquiry, since it is mentioned but infrequently in the clinical history of patients: but published examples of heredity are not difficult to find, running in a few instances through more than two generations. In the present series a female, aged 35, with multiple lipomas on the arms, gave a family history of lipoma in mother and grandfather.

The relation between lipoma and nerves has often been noted, but the significance is undecided. The relationship is suggested by some tumours which are symmetrically distributed and a few which have followed a spinal injury. More definite relationship is shown by a minority of tumours which are painful, resembling the fat-hypertrophy of Dercum's disease. Adair et al. (1932) went so far as to suggest that multiple lipomas might be neurolipomas. They described the multiple type as being firmer in texture and not usually adherent to the skin. They drew a clinical analogy between multiple lipomas and multiple neurofibromatosis, both being multicentric, often symmetrical, and with a similar distribution. The two diseases are known to coexist in the same patient, and both may be associated with skin pigmentation and melanomas. The clinical resemblance may be strikingly similar.

The relation of the fat contained in a lipoma to that of the body metabolism has long been a matter of great interest, but the solution is still unknown. Wells (1912) concluded that there was no detectable chemical difference from normal fat. There appears to be no anatomical reason for the apparent isolation so well marked in the paradoxical condition of a growing fatty tumour, such as liposarcoma, and the adjacent wasting body. Wells puts forward the ingenious idea that the processes of laying down and giving up fat depend on cell differentiation and are not merely reversible physical or chemical processes.

CLASSIFICATION

The number of cases collected for study in this series amounts to 170.

Both sexes are liable to develop lipomas, but with few exceptions the published records indicate a greater predisposition for females (in the present series 2 : 1). Geschickter (1934), in a series of 390 from the Johns Hopkins Hospital, gives the ratio as 3 : 2, whereas in the figures of Adair et al. (1932) 73% were females. The reason for this sex tendency has been variously stated to be either cosmetic or a greater tendency of females to develop abnormalities of adipose tissue possibly hormonal in origin.

Lipomas are seen at all ages but especially in middle life; only 10% occur in children according to Geschickter (1934). Some seem to be congenital, many examples having been reported. Some of these show progressive growth and may attain a large size indicating their neoplastic nature—e.g., a tumour of five years' duration on the back of the thigh and measuring 4 × 3 in. in a boy aged 13, in the present series. Others show heterotopic tissue or are mingled with normal structures of the affected part. Probably many of these are not true tumours but hamartomas—superfluous tumour-like masses of improperly blended tissue comparable to most angiomas (Willis 1948). From table I it can be seen that three-quarters of the present series occurred between the ages of 30 and 50, although allowance must be made for the time of tumour growth. This applies not only to the whole series but also to each sex after separation. There is no indication that they tend to appear at times of hormonal imbalance such as puberty and the menopause.

TABLE I—AGE-INCIDENCE OF LIPOMAS

Age (yr.)	Males	Females
0–9	1	3
10–19	2	2
20–29	0	14
30–39	9	25
40–49	14	28
50–59	20	31
60–69	8	11
70–79	0	1
80–89	1	0
Total	55	115

The duration of tumour growth is variable, but it is not uncommon to hear of a period of growth followed by arrest for many years. In the present series it varied from a few months to forty years.

TABLE II—SITES OF 182 LIPOMAS IN 170 PATIENTS (EXCLUDING MULTIPLE OF FOREARMS)

Site	No.	Site	No.
Shoulders	33	Forearm	8
Back	28	Abdominal wall	7
Thigh	23	Chest wall	6
Neck	16	Leg	6
Head	14	Visceral	4
Buttock	10	Other sites	9
Arm	9		
Axilla	9	Total	18

In their discussion on lipomas Adair et al. (1932) grouped their cases into four clinicopathological types: (1) single, (2) multiple, (3) congenital diffuse lipomatosis, and (4) degenerate lipomas. This was a classification of convenience, as they pointed out. The distinction of the first two groups remains unproved, and the fourth is a subgroup rather than a separate entity. Geschickter also used a clinicopathological classification for his series of lipoid tumours, dividing them into three groups—lipoma, recurrent lipoma, and liposarcoma. The merits and faults of these classifications will not be pursued, but for practical purposes ordinary lipomas may conveniently be classified on an anatomical basis according to the tissue plane or organ in which they lie. The following classification is suggested:

- (1) *Subcutaneous:* Subcutaneous
  - Breast
- (2) *Interstitial:* Subfascial
  - Intramuscular
  - Intermuscular
  - Subsynovial
  - Parosteal
  - Myelogenous
- (3) *Visceral:* Respiratory, Gastro-intestinal, Genito-urinary } Submucous, Subserous
- (4) *Thoracic:* Mediastinal
  - Subpleural
- (5) *Abdominal:* Retroperitoneal
  - Perirenal
  - Mesenteric
  - Broad ligament
- (6) *Nervous:* Cerebral
  - Spinal } Intradural (Intramedullary, Extramedullary, Radicular); Extradural (Congenital, Acquired)
  - (Peripheral Multiple Subcutaneous)

CLINICAL FEATURES

The commonest site is the subcutaneous tissue (figs. 1 and 2). In this situation the classical signs can easily be elicited of a soft, or elastic, lobulated swelling exhibiting translucency and in many cases a fine attachment to the skin. Because fat is a good insulator, the surface of many lipomas, particularly the larger variety, feels cooler than a symmetrical part on the other side of the body. For the most part symptoms are few and pain is inconspicuous except in a minority. The relation to nerves has been previously mentioned, but the reason for the pain is uncertain. Both congestion of the tumour and interstitial neuritis have been suggested but without proof. Alternatively both pain and lipoma may be secondary to some more distant nervous defect.

Comparison of the sites of subcutaneous lipomas in this series with those tabled (table II) by Geschickter (1934) shows a striking similarity. In both series the shoulder, the back, the back of the neck, and the thighs are the commonest sites. A possible reason for this has already been discussed.

Pedunculation is an interesting feature of a few lipomas of long standing. In the present series there were only 3 such cases,

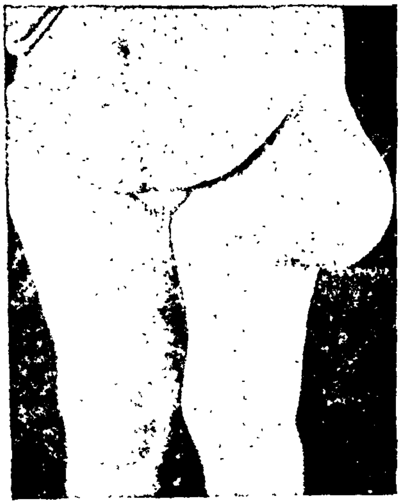

Fig. 1—Subcutaneous lipoma on upper and outer side of left thigh in a woman aged 69.
